1.0 Introduction to the MS10 and MS1

The MS10 is a complete portable Audio Test Set that combines the functions of an Oscillator (Signal Generator), Level Meter, Peak Programme Meter, Noise Meter and Distortion Meter, along with Frequency, Phase, and tape speed measurement, in one small hand-held unit that can be used on its own or with a computer running the 'Lin4Win' support software (supplied free).

Its main feature though is 'Sequence Testing', introduced by Lindos twenty years ago in the LA100 test set, and universally used by broadcasters and studios for routine quality assurance ever since. It takes just two button presses (SEQ followed by 3 for example) to run a typical test sequence that can quantify any audio system in terms of levels, frequency response, phase, distortion and noise in as little as twenty seconds, with results stored in the unit. If a PC is connected, running Lin4Win, an impressive results sheet with graphs and pass/fail tolerance testing appears immediately on the screen ready to save, print, or even publish to the Web on our Test Sheet Database for all to see! Because sequence tests carry (FSK) coded information they are self-synchronising and fully automatic, even between any two MiniSonic units on opposite sides of the world!

The emphasis throughout is on *subjectively meaningful* tests and one set of quality standards, with only quasi-peak weighted (ITU-468) measurement of both noise and distortion residue supported. This gives readings that are pretty representative of what you will hear, whether you are testing a CD player, an amplifier with crossover distortion (long considered impossible to quantify - but we don't agree), or a loudspeaker. With comparable measurements, and a database fed by you, the user, we aim to challenge much of the hype and make-believe that has taken over the audio world.

The MS1 is simply an MS10 with sequence reading disabled (except for a sweep), sold at a price that is more affordable by schools and enthusiasts. As sequence generation (which includes some LA100 compatible sequences) is not disabled, it can also function as a low-cost generator for use with the MS10 or LA100. The MS1 is easily upgraded to an MS10 by plugging in a new firmware chip behind the removable 'chiplid' on the front panel.

1.1 Getting Started

Most users will not want to read through this manual, which is laid out as a comprehensive reference guide, before getting started, so we suggest working through the following brief tutorial as a quick way of becoming familiar with the essentials.

1 Connect the Osc (output) and Input sockets together, using the Unison to XLR leads provided, and Set the MIC/LINE toggle switch to **LINE**. If you are

using phono (RCA) or other 'single-ended' leads, note the automatic change to consumer levels (see the UniSon section for full details).

2 Switch the unit on with the top right-hand toggle switch and check that the display lights up. The unit will power-down (into 'sleep' mode) if no key is pressed for 4 minutes: just press any key to restore operation.

3 Turn up the Volume with the slider control and you should hear a 1kHz tone. Do not be disconcerted by the changing levels - the unit starts up in PPM (Peak Programme Meter) mode and generates a line-up sequence to facilitate use in certain fixed studio applications. Note how the changing L (left) channel level is shown by a bright bar and the R channel level by a dimmer 'shadowbar'. The speaker always monitors the L channel in level mode, but is switched to the selected channel for Noise, Distortion etc.

4 Press LEVEL. This is the normal mode for measurements (faster response than PPM mode). The output now goes to 1kHz at 0dBu on both channels and both display bars merge reading 0dB on the bottom scale.

5 Hold FREQ down and press < or > to change the oscillator frequency. The shadowbar now indicates the frequency being generated (top scale) and the main bar shows the measured level on the L channel. Hold FINE instead and the frequency changes in finer 1/12th octave steps. Hold dB and press < or > to change the output level (1dB steps). Note that both these functions 'wrap' at both ends to cover a huge range if desired. If this seems confusing, don't worry, as things are much more easily understood when you use a PC!

6 Press keys 3 & 4 together to reset and note how the battery voltage is displayed if you hold them down (by the main bar – the 'blurr' shows the low zone). There is currently no low-battery indication, so check battery voltage from time to time. The oscillator output is now restored to 1kHz @ 0dBu.

7 Press Noise. The oscillator automatically mutes and the reading drops to the lowest ('under') mark on the scale. Note that on the bottom scale 0db now represents -50dB (L chan). If you were measuring a good 16-bit digital system you might expect to see a reading of -16dB corresponding to -66dB (468-wtd quasi-pk). You are measuring the noise level of the MS10 oscillator output which is around -82dB and hence off the bottom off the scale (but not when range changing is used). Press L or R to select either channel.

8 Press Dist. The unit will momentarily normalise the level, and then display relative distortion (468 wtd quasi-pk). Again, the reading should be off the bottom of the scale.

9 Press SEQ to enter sequence mode, and then press KEY1. This will run sequence 1, which is a 5 second sweep. Note the audible FSK signal at the start, which signals the start of the measurement and the segment type. Once the sweep has finished you can use the < and > keys to move the cursor (shadowbar) up and down the frequency scale and read off the stored levels

on the main bar. Holding SEQ and pressing R allows the R channel results to be viewed. As you have a simple direct connection of course the levels will be the same at all frequencies. Press LEV to leave sequence mode. This completes a quick tour of manual stand-alone capabilities; now try out operation with a computer:

10 Install Lin4Win on a PC (click on the CD drive and then double-click on the 'setup.exe') and connect the Minisonic using the RS232 cable. Start Lin4Win (from Start/All Programs menu). The control panel should open and a status bar at the bottom left should show when connection has been established. If the box keeps flashing red you may need to change the COM PORT setting (menu options/coms setting). You are now ready to play with the many features of the control panel which are largely self-evident.

11 Press SEQ on the unit followed by KEY3. This will run a 20-second sequence of segments (n,u,r,q,z) and on completion you should see full listings, with graphs, appear in the results window. Note that you can double click on both the text and the graphs to bring up options and an expanded graph with cursor readout. This demonstrates the full power of sequence testing, which for many purposes may be all that you need to use. You can now experiment with running other sequences, either from the keys, or by entering any sequence of up to six segment letters (but note restrictions) in the text box on the control panel under the RUN button. MiniSonic segments must be entered as lower case letters as some LA100 segments also run on the MS10. Press Return or click RUN to start the sequence.

Try out SEGh which produces an interesting (headroom) graph showing the level at which a piece of equipment starts to limit or clip. To save results use the shortcut CTRL-S. To open a saved file use CTRL-O. To print results use CTRL-P. You will have to specify directories for saving in the usual way, and it is a good idea to create a 'Results' directory first. Note that tolerances and comments can be added.

You are now ready to test a piece of actual equipment. In some cases this will require both the input and the output to be connected to the MS10. In others, such as when testing a sound card output or a CD player, only the input of the MS10 will be connected, the test signal coming from recordings of test sequences or tones which are available as downloads from the www.lindos.co.uk website.

What follows is a detailed reference guide to the various functions of the MS10 but you may find it more useful to skip to Section 4 for full details of Sequence Testing, or Sections 9,10,11 which explain in detail how to test various specific types of equipment.

2.0 Power On/Off and Basics

The unit is powered when the right-hand toggle switch is down. If no key is pressed for 4-minutes it will automatically enter 'sleep' mode and the display will go out. Press (don't tap) any key to restore operation from sleep mode. Battery life in sleep mode is over 5000hrs and both the working state and any stored results are retained. Using the toggle switch to turn the unit on and off will save battery life and ensure total reset, but any saved results will be lost. To put the unit into sleep mode press keys 1 and 2 together. If any external devices are taking power from the 'UniSon' input or output connectors this is not turned off in sleep mode – toggle the power off to avoid a flat battery!

To disable automatic turn-off use startup option 1. The startup options (which can be used together in combination) are:

Startup Option 1 – Power Lock (Hold Key1 while turning the power on) disables auto-turn-off so the unit stays on until the battery runs down. The unit also starts up muted – useful when testing speakers.

Startup Option 2 – Channel Ident (Hold Key2 while turning power on). This changes the startup sequence from SEGj to SEGi (alternative line-up test).

Startup Option 3 – Glits Tones (Hold Key3 while turning power on). This alters the start-up sequence to GLITS (as used by the BBC).

Startup Option 4 – Direct Trigger (Hold Key4 while turning power on) enables Direct Trigger in sequence mode, meaning that segment characters are passed internally from generator to measuring set, rather than by FSK (frequency shift keyed) signalling over the measurement path. This is useful for testing devices that attenuate frequencies in the 1650 to 1850Hz region used by the FSK, such as sub-woofers, and crossover-filters. Sequence measurement commences when a key is pressed to send the sequence or segment, even if no signal path exists.

Startup Option 9 – LA100 Sequence Generation (Hold SEQ while turning the power on). This selects LA100-compatible sequence generation in sequence mode for inter-working with the earlier Lindos LA100 test set. See section 4.5 for full details of the LA100 sequences available. Recognition of LA100 segments works without setting this option, though only to a limited extent in this firmware version (M3.0).

2.1 Reset

Pressing KEY3 and KEY4 together resets the unit to start-up conditions. The display flashes momentarily into battery test, the oscillator resets to 0dB and 1kHz output, and Level mode is set. The sequence data and results listing are cleared, but power-lock is not cleared. Pressing LEVEL performs a lower level of reset, cancelling relative reading, range settings, level options and vernier mode and selecting both channels, so when you press LEVEL you can be

sure that you are simply reading levels, though oscillator settings and sequence results are not reset. Pressing any of the function keys – Level, Noise, Dist, Seq, PPM, cancels any options or range settings, ensuring a consistent basic reading for ease of stand-alone use.

2.2 Monitor Volume

The speaker enables the measured signal to be heard at a loudness level set by a small slider VOL control on top of the case. Only the left internal channel is monitored in Level or PPM modes, but plugging in headphones disables the speaker and allows high-quality listening in stereo. In other modes the speaker monitors the selected channel and is often useful because it enables the nature of noise or distortion residues, or the progress of a sequence test to be heard.

2.3 The ‘Line-Up’ Sequence

A special, repeating, ‘line-up and channel-ident’ sequence is generated at power switch-on (to allow fixed use as a line-up generator in broadcast applications). Line-up sequences are often recorded at the start of programme material as confirmation of alignment level and channel assignment for broadcasting. Currently SEGj is used, which increases the level to +8dB on the L channel first, then on both channels. It combines the ability to identify L and R channels heard together or in isolation, with a check of max level (PPM6 is +8dB), but this can be easily changed on request to the ‘GLITS’ or other tests (contact Lindos for special firmware chip). To stop the line-up sequence press LEV (or NOISE or DIST) and normal oscillator operation will take over.

2.4 Battery / External Powering and Charging

Hold down keys 3 and 4 together to read the battery voltage. On a fully charged battery (8.3V) the main bar should be at maximum (RH red LED lit), and as the voltage drops the indication will fall until it enters the patterned ‘no go’ zone at about 6V. The unit will cut out suddenly at around 5.5V, and at present no other battery-low warning is given. Over 16 hrs of use should be possible on the 1.85 A-hr battery supplied.

The MiniSonic may be powered externally using the 12V mains adapter supplied by us (100 to 240V supply) or any other power supply, preferably of the regulated type. The power connector is 1.6mm centre positive and protected against reverse polarity. Powering from a car battery is also permissible, the internal regulator taking care of voltages up to 14. Current consumption is only 100mA, but rises to 300mA when charging a flat battery. The Lithium Ion battery charges whenever external power is connected, the charge rate reducing to zero as full charge is approached so that continuous use on external power will not degrade battery life at all. External fast-charging in one of the many available camcorder battery chargers is also possible, as is

the use of the bigger capacity batteries that are available with compatible (Sony) fitting (versions with or without 'Info-Lithium' are suitable).

Note that the unit will turn on as soon as external power is applied, even with the toggle set to off, (to facilitate use in fixed installations as a PPM, alignment tone generator etc), with auto-turn-off automatically inhibited. Since the latter is achieved by sensing whether the voltage is sufficient to light the top red indicator on the battery test (around 8.1V), auto-turn-off is also disabled on a well-charged battery. Switching the toggle to ON provides battery backup in the event of brief power failure. Lithium Ion batteries normally retain charge for at least a year, even when they are several years old (expected life is over ten years), and are internally protected against over-discharge etc. Operation from a PP3 Alkaline battery is possible (5hrs intermittent use) (request adapter lead from Lindos or use a diode in series to prevent explosion through charging!) A PowerBus for external microphone preamps and other devices is provided on pin 5 of all input and output (UniSon) sockets. This is at 6 - 8V, (for regulation to 5V in the device) current limited at 1 - 1.5A for safety (sometimes this pin may be accidentally grounded by contact with the connector shell as it is inserted, in which case the unit will be seen to reset due to brief loss of power). Powering the MS10 via the UniSon PowerBus, without a battery, is also possible.

3.0 Stand-Alone Use (No computer connected)

Connect the Osc (output) and Input sockets to the unit to be tested using the leads supplied as appropriate: Unison to XLR for professional equipment or Unison to Phono for consumer equipment. Other leads such as Unison to 3.5mm Mini-jack (for computers and portable devices), or Unison to Jack (small tip for broadcast or large tip for guitar amps etc) are available from Lindos.

ENSURE THAT THE MIC/LINE TOGGLE IS SET TO LINE (unless microphone operation is required, or results will read 6dB low!).

3.1 Level Measurement

Press LEVEL. The range is fixed (0dB) and covers -20 to +10dB relative to alignment level, which corresponds to 0dBu (0.775V rms) with balanced leads (XLR), but -6dBu (Lindos Unison standard) when unbalanced (phono or mini-jack) leads are used. Both channels are displayed - the bright bar indicates the L channel, while the 'shadowbar' shows the R channel - but just one may be selected using the L or R buttons. Pressing LEVEL (or L and R together) restores both channels. Although levels are only indicated to the nearest 1dB they can easily be read to 0.05dB resolution (indicated on the shadowbar) using the novel 'Vernier' facility (see section 5.1). Normalising and range

changing are also possible (see 5.3 and 5.4). Level measurements use a rectifier with fast Quasi-Peak characteristics, not true rms (root mean square). For most measurements, on sine wave signals, this is of no consequence, and the readings correspond to rms value. The term Quasi-Peak refers to any rectifier (detector) that responds essentially to the peak of the signal, but takes a significant time to respond (integration time). Increasing the input to a digital system beyond the clipping limit would continue to produce an increasing output reading on a true-rms rectifier, as the waveform became flattened, but a Quasi-Peak reading ceases to rise abruptly at the rms sine-wave equivalent of the clipping level. This is a very useful feature, made use of in the special headroom test segment (SEGH).

Level Option 1 – Phase (press LEV and key1 together). This selects phase display on the unit (see section 3.6).

Level Option 2 – Ultra-Fast Level (press LEV and key2 together). This selects level measurement with a very fast response; reducing attack and decay times by a factor of ten, which may prove useful when making rapid adjustments.

Level Option 3 – Frequency (press LEV and key3 together). This selects frequency display on the unit (see section 3.5).

Level Option 4 – Vernier Mode (press LEV and key4 together). This selects 'vernier' mode for high resolution (see section 5.1).

3.2 Noise Measurement

Press NOISE. The range is fixed (-50dB, meaning that 0 on the bottom scale corresponds to -50dBu), and so covers -70 to -40dBu. Readings are of absolute level, unless the REL indicator is flashing. To read noise relative to the test level, press DIST, wait a second, and then press NOISE. This is just a convenient way to save the 'Test Level', which is the reading for the current oscillator setting, as a Reference Level; a process called Normalising (see 5.3 for more details). Only the left channel is displayed, (the MS10 includes only one set of measurement filters) but pressing R selects the other channel. Pressing NOISE (or L) restores L channel operation. The oscillator output is automatically muted (though it can be de-muted) and measurements are ITU-468 Weighted (formerly CCIR468-4 plus IEC and BS standards), with the exception that the Quasi-Peak response has been given a faster decay time for quick settling (tone-burst response times are still to 468 specification). The NOISE key may be held down for a true 468 decay time, though this will normally make no difference unless successive impulsive noises - clicks and pops - occur within a few seconds of each other; a situation that used to concern engineers working with telephone links and is now something to watch for on computer sound card outputs. The use of a faster decay time, together with a brief initial fast-settling period (also invoked on range-changes when used with a PC), makes 468 Quasi-Peak measurement much more

user-friendly. Where other instruments may take many seconds to settle to a stable reading, the MS10 is so fast that it is even possible to take readings during brief pauses in actual programme material.

Noise is often expressed as 'Signal to Noise Ratio' or 'Dynamic Range', but these terms are confusing, as they do not refer to any standard method. There is no such thing as 'signal level' on music or speech except from moment to moment! Dynamic range is often taken to mean the difference between max signal level and noise level, but it is also used to refer to the difference between max signal level (full scale digital) and muted noise level (without dither and hence just analog output noise) on CD players. This is too confusing, especially since many CD players use output muting in the absence of signal to achieve an even lower level.

What really matters is how far the noise is below a typical signal, and though there is really no such thing as a typical signal level, it is a good idea to establish a nominal one, call it 'alignment level' (AL) and measure noise relative to this. All broadcast measurements are made relative to 'alignment level', which usually corresponds to 0dBu (0.775Vrms) on all analog paths. Maximum permitted level, or full-scale digital (FS), will be above this by an amount referred to as 'Headroom', usually 18dB (EBU recommendation) on digital recordings, or 24dB on some original material. Headroom is typically 12dB or less on broadcast paths, where the EBU recommends +9dB max level when measured on a PPM (which does not read the true peaks).

The great merit of this system is that a noise measurement made relative to Alignment Level will always be a reasonable guide to the true intrusiveness of the noise onto typical material, regardless of the headroom. Where less headroom is available for transmission, compression or limiting will usually be used to reduce brief peaks, but this has little effect on overall perceived loudness. A recording may start life with 24dB of headroom, and end up with only 9dB of headroom at the listener's radio or television. Its 'dynamic range' has indeed been reduced, but it will not sound any noisier, assuming that it is the peaks that have been limited. Instead it will have lost 'sparkle' and impact. Specifying noise and headroom separately reflects these different qualities properly.

Noise Option 2 – Crosstalk (press NOISE and key 2 together). This selects Crosstalk measurement (see section 3.4).

Noise Option 3 – True ITU-468 Q-pk (press NOISE and key 3 together).

This selects the correct (slower) decay on the quasi-pk rectifier.

3.3 Distortion Residue Measurement

Press DIST. The oscillator will generate 1kHz and the unit will very briefly measure the level of the incoming tone, saving it as a reference level and then switching to relative-level mode as shown by the dBu/Rel indicator flashing.

This is also called 'normalising'. The distortion-residue level is then indicated on a fixed range (-40dB) (corresponding to 0 on the bottom scale), which therefore allows readings of -60 to -30dB to be made. Only the left channel is displayed, unless R is pressed. Pressing DIST or L restores left channel operation. The oscillator output is automatically set to 1kHz, but any level may be set as required. What is measured is the relative level of all harmonics and noise in the frequency range 2kHz to 20kHz, using 468-weighting and quasi-peak response (a method strongly favoured by Lindos and also incorporated into the IEC-268 standard). The dBu/REL button toggles relative measurement on and off, allowing the absolute level of distortion-residue to be read if desired. The detailed merits of weighted distortion-residue measurement are discussed in later sections, but essentially the method takes proper account of the high order harmonics caused by crossover distortion or digital quantising errors, and also gives due emphasis to the high frequency modulation noise that can cause a characteristic 'roughness' on tape or compact cassette. Distortion-residue readings will generally be higher than if they were measured using the commonly quoted THD (total harmonic distortion rms) method, and on harsh crossover-distortion they may be 15 or 20 dB higher. Furthermore, readings may be much higher than those commonly quoted in equipment specifications because the latter often refer to measurement at maximum output level or full scale digital level, a practice that is to be condemned as it gives high figures but does not reveal what really matters. A typical DIST measurement on a 16-bit system might read -20 (representing -60dB) but compact cassette will read +5 (-35dB) or higher, so the fixed scale has been chosen to encompass this large variation. Use range-changing (section 5.4) if the reading is off the scale. To measure relative distortion residue at levels other than 0dB, just set the required oscillator output level before pressing DIST.

3.4 Crosstalk Measurement (NOISE option 2)

Press NOISE and 2 together (two LEDs will light up). Operation is exactly as for noise, with the same 468-Weighting and Q-Pk response, but one channel of the oscillator output is always muted while the other is driven at the set level and frequency, which may be adjusted while reading crosstalk. Measurements are of absolute level, unless a reference level has been saved by 'normalising' (or previously pressing DIST which normalises), in which case the REL indicator will be flashing.

Crosstalk can be measured at any frequency or level, simply by changing the oscillator settings, but note that the measurement is 468-Weighted, which greatly emphasises readings around 6.3kHz (by 12.2dB). Use of the automatic sequence test for crosstalk (SEGc) is recommended as this automatically changes the test level to give results that comply with a standard originally devised by the IBA (Independent Broadcasting Authority (UK) now disbanded) for broadcast testing, with regard to both the (milder) IBA-recommended

weighting curve and the maximum permitted levels that apply where 50us pre-emphasis is in use (such as on FM transmitters).

3.5 Frequency Measurement (LEV option 3)

Press LEVEL and key 3 together. The LEVEL indicator will flash to remind you that the 'shadowbar' (which appears feinter) now indicates frequency (to the nearest third octave) on the top scale. The level is displayed simultaneously by the main bar, for the L channel only, unless R has been pressed to select the other channel. Though not very precise, the frequency readout is graphic and fast: very useful for identifying frequency bands on test tapes or disks. Precise frequency measurement is available when using Lin4WinXP on a PC. Note that frequency is only read on the left channel.

3.6 Phase Measurement (LEV option 1)

Press LEVEL and key 1 together. The LEVEL and DIST indicators will flash to indicate that PHASE measurement is selected. The main bar will indicate the level on the selected channel while the 'shadowbar' will indicate the phase difference between the channels on a scale centred around the 0dB mark with 20 degrees per division. Thus 0 indicates zero phase difference, and +1 indicates +20 degrees, while +9 corresponds to the maximum of +180 degrees, and -9 to the minimum of -180 degrees. Phase measurement works up to 40kHz and down to about 40Hz. Note that the left channel is considered the reference so that a +ve reading indicates that R channel leads the left and a -ve reading means that the R channel lags behind the left. This was chosen because the L channel is used for FSK signalling on sequences and so is the preferred channel to use as a directly connected reference when measuring absolute phase in-out on a piece of equipment. Phase difference between channels causes shifting of the stereo image, and is a useful measurement to make when checking the azimuth alignment of heads on analog tape machines. There are circumstances though in which the phase delay in a single channel is of interest, for example when attempting to 'time align' separate drivers in a wide range loudspeaker. In this case, the left channel input and output of the MiniSonic should be connected directly and treated as the reference signal (by plugging the XLR's together or by making up a special lead incorporating the link. The R channel input is then connected to the output of the device under test (crossover network etc) so that what is displayed becomes the input-to-output phase shift.

For microphone measurements a special trick can be used taking advantage of the fact that when MIC is selected on the MiniSonic, the -ve UniSon inputs remain functional and any input to them is summed with the Microphone signal. A single wire connection between the -ve output and -ve input of the left channel can therefore be used to provide a reference signal, allowing absolute phase to be measured using a microphone plugged into the right mic input. Do not attempt to use the standard XLR input lead to achieve this

(capacitive coupling in the lead to the floating +ve input will cause problems). A D-type plug with a single wire to pin 1 (from pin 1 on the output connector) is required (or Lindos can supply a special lead-set). Using such a set-up, the microphone will show phase at a given distance from a speaker. Alternatively it is possible to use two microphones and simply observe the phase difference between them. This can be useful for checking the time alignment of a sub-woofer for example, with one mic placed by the sub-woofer and the other by the main speaker.

3.7 PPM (Peak Programme Meter) Use

Press PPM. Both channels are displayed with accurate IEC (type IIb ie UK/BBC – British Broadcasting Corporation) dynamics, so this mode is ideal for checking the legality of programme levels for broadcast or recording. The range is set to 0dB on pressing PPM for use with standard broadcast levels, but the input gain may be adjusted by holding down the PPM key and using the up-down (L-R) keys. While PPM is held, the ‘shadowbar’ displays the gain setting. Note that it ‘wraps’ at top and bottom allowing gain settings from -50 to +30dB; if you step up the gain, for example, beyond +9 the shadowbar will jump to -20, and then continue up to 0 corresponding to +30dB gain. The LINE OUT UniSon socket provides a gain-controlled output for recording purposes, with alignment level 0dBu out at PPM4 (0dB on the scale). Selecting MIC on the toggle turns this mode into a microphone recording set-up for voice-overs, location recording etc. Note that +8dB corresponds to PPM6 or maximum permitted level for broadcast material (EBU absolute max is +9dB), while 0dB is PPM4 or ‘normal’ level. A self-adhesive label with clear standard PPM markings (1 to 7) can be supplied by Lindos for sticking on top of the frequency scale, if this is preferred. A scale centred conventionally on PPM4 is also possible (consult Lindos for special firmware chip).

PPM Option 2 – Fast attack PPM (press PPM and key 2 together) provides an alternative PPM with very fast attack (integration time of under 1ms) on both channels. Decay time is as standard.

PPM Option 3 – Dual Speed PPM (press PPM and key 3 together) selects a dual-attack PPM operating from the L channel only. The main bar retains standard PPM characteristics while the ‘shadowbar’ has the very fast attack of option 2. This will be found useful for detecting whether brief peaks have been compressed. On uncompressed live percussive sounds a difference of 5 to 15dB will be observed between the two readings, as can be demonstrated by simply plugging a Lindos miniature microphone into the left MIC socket, selecting MIC, and banging two spoons together! This test demonstrates convincingly why recording with realism requires 18dB or more of headroom for the brief loud peaks that have little effect on perceived loudness (the ear has a reduced response to brief bursts), yet are vital to maintain ‘sparkle’ on percussive sounds. Using this mode to check recordings will reveal the extent to which brief peaks have been limited or compressed. Unfortunately, on

broadcasts and a great many recent CD's the two bars will rarely be seen to separate by more than 1 or 2dB!

PPM Option 4 – Tape Speed and Flutter (press PPM and key4 together) selects speed and flutter measurement (see below).

3.8 Tape Speed and Flutter (PPM option 4)

Press PPM and key 4 together to select this mode. The PPM and DIST LED's should light up. The shadowbar indicates deviation in speed (on a 3.15kHz tone) with readings centred on the 0dB mark and sensitivity of 0.2% per division (+2% to -4% scale range). Outside this range a 'rolling' pattern may appear.

Tape flutter (*not currently implemented – later upgrade?*), (also known as 'Wow and Flutter' is measured weighted quasi-pk to IEC386 and indicated by the main bar in dB, with 0dB representing 0.1%, so that +10dB represents 0.3% and -10dB 0.03%. While wow and flutter used to be treated separately, with wow referring to slow speed variations below about 1Hz and flutter to the faster variations, the use of the weighting curve now allows a single meaningful measurement. The curve peaks at 4Hz (the most annoying variation) rolling off at higher and lower frequencies.

3.9 Oscillator Use

Setting The Output Frequency

Oscillator setting is best demonstrated in LEVEL mode, though it works in other modes. Hold FREQ while operating the up-down (L-R) keys to change the frequency in 1/3-Octave steps. The 'shadowbar' will temporarily become a cursor indicating the selected frequency (top scale), while the main bar continues to read the L channel input level normally. Hold FINE, instead of FREQ, to change the frequency in 1/12-octave steps. Note that the cursor 'wraps' at both ends in such a way as to allow frequencies down to 4Hz and up to 40kHz to be set. Just above 40kHz will be found 1kHz, 5kHz, and 10kHz square waves and just below 4Hz is generator mute. At reset or switch-on the oscillator is set to 1kHz at 0dB.

Setting the Output Level

Hold dB while operating the up-down keys to change the level in 1dB steps, again indicated by the 'shadowbar' acting as a cursor. Again, the cursor 'wraps' at both ends, allowing levels between -90 and +19dBu to be set. If this confuses, just reset and try again.

Channel Selection and Mute

Press MUTE to silence the output. Press again to restore both channels (or press dB). Hold MUTE and press L (or R) to output on the L (or R) channel only (may need two attempts – only works after muting).

4.0 Sequence Testing

Lindos Sequence Testing is a powerful innovation, first incorporated into the LA100 in 1984 and universally used by broadcasters worldwide ever since. A MiniSonic Sequence consists of up to six segments; where segments are like building blocks that can be chosen by the user. Each segment generates a particular sequence of tones, a sweep, or silence, intended to test a particular parameter, such as frequency response, distortion or noise. It begins by sending its identifying character, (in ASCII code) as a frequency-shift-keyed (FSK 110-baud) signal which acts as a synchronising trigger as well as the instruction for a series of timed measurements. This means of course that the responding MiniSonic does not have to be the one generating the sequence; it doesn't even have to be on the same side of the world but may be at the other end of a satellite link or line.

Because the measuring side of a MiniSonic unit operates quite independently from the generating side, the signal may be delayed; by a fraction of a second, as is the case when testing two-head tape machines, or by years, as when playing back a tape that has had a sequence test recorded on it for future quality checking. Any MiniSonic unit in SEQ mode will respond instantly to an appropriate FSK signal at its input, and go into the appropriate series of measurements for the specified segment. At the end of each segment it waits for up to one second for the next segment, and when no more segments are detected it times out with the results saved in its memory for viewing or printing. If a PC running Lin4Win is connected, the results will appear on the screen about a second after the sequence has finished running, in the form of a Results Sheet that can be saved or printed as an A4 page. Sequence 1 for example, will produce a 1/6th-octave plot of frequency response, for two channels, in just five seconds. Sequence 3 will produce a complete set of results, with graphs and bar charts, of frequency response, relative phase, test levels, noise, and distortion at six levels, in just 20 seconds. Many other variations are possible by combining segments, especially when using the Lin4Win support software running on a PC (see section 10).

4.1 Inter-working with the LA100

The MS10 normally uses segments that are different from those recognised by the LA100, because its design made a faster and better set possible. MiniSonic segments take advantage of the MS10's ability to measure levels on both channels simultaneously as well as its 'smart-rectifier' which changes speed for fast settling on all measurements. The Dist Residue segments (q and r) in particular provide a powerful test of weighted distortion at six levels, which is not practicable on the LA100 because of settling limitations.

To distinguish them from LA100 segments, MiniSonic segments are characterised by lower-case characters (the LA100 uses mostly capitals). They are only sent once, both channels being measured simultaneously on

sweeps, or in rapid succession during other segments (the LA100 sends each segment twice, once for each channel). Segments only start with a single FSK character (the LA100 generally uses two, the first being a channel specifier). Where the LA100 uses a 'stop' character to mark the end of a sequence, the MiniSonic simply waits one second after it has finished logging each segment, and times out (bringing up results) if further FSK is not detected in this time. These innovations make for much faster testing.

Recognising that it might nevertheless be useful to use the MS10 in an LA100 environment (especially on lines and links), a degree of compatibility has now been achieved, by providing for generation of the most commonly used LA100 segments. Lin4Win now distinguishes the appropriate upper-case letters entered in the run box from normal lower-case MiniSonic segments, enabling a variety of LA100 sequences to be set up (enter each letter only once – it will automatically run twice where appropriate). For stand-alone use the MS10 can be put into 'LA100 mode' using startup option 9 (hold SEQ and turn on the power). Keys 1 to 4 then run four popular LA100 sequences, rather than MiniSonic sequences, when in SEQ mode (see sections 4.4 and 4.5 for listings), making the MS10 a useful partner to the LA102 measuring set for network testing. The recognition and logging of a few LA100 segments has also been added (SEGS T,V,U,R,N) but further work is needed for these to work reliably in actual LA100 generated sequences (currently the MS10 will time out on segments it cannot recognise, and is confused by some of the sequences or text headers normally sent by the LA101).

4.2 Running a Sequence

Press SEQ to put the unit into sequence read mode. The bar display now indicates the contents of the memory from the last frequency response sweep that was run (or nothing). To run a sequence simply press one of the number keys 1 to 4 (see below for SEQ 5 to 13). A sequence of test Segments is generated, and assuming that a path exists to the input of the MS10 this will be responded to. If a PC running Lin4Win is connected, then completion of the sequence is indicated by the appearance of a results page on the screen. Alternatively, it may be of interest to follow the progress of a sequence by turning up the volume control and listening, or by watching the MiniSonic bar display. The 'shadowbar' acts as a progress indicator, moving from left to right for each segment, while the main bar indicates the instantaneous value of the measurement. The SEQ indicator flashes while a sequence is being generated, and stops when sequence generation ends. The REL indicator flashes if master-seg m or n is responded to, to indicate that relative reading is in progress. Note that the FSK trigger is only recognised on the left channel, and that it requires a path that can transmit signals around 1.8 kHz. Use 'direct trigger' (startup option 4) to test low-frequency-only paths, such as sub-woofers or crossover filters. FSK operation means of course that another MiniSonic may be used for measurement, even at the distant end of a line or

satellite link. Loudspeaker measurements can also be made conveniently. In-car speaker responses may be measured, for example, by playing a sweep segment from a test tape or CD (available from Lindos, or as a download), with automatic triggering from the microphone signal so that no electrical connection is required. Computer Sound-Cards and MP3 players can be tested using downloaded test sequence files (available at www.lindos.co.uk). All sequence levels are generated relative to the basic oscillator level set prior to running them (0dBu unless altered). To ensure that this is 0dB, if in doubt, just do a reset (keys 3 and 4) prior to entering sequence mode. In some instances, of course, it will be desirable to run a sequence at a chosen level, for example when testing low-level microphone inputs.

4.3 Choosing Sequences and Segments

Sequences 1 to 4 are ordered according to complexity (and time taken). SEQ3 is probably the most useful, as it tests most things in 20 secs, but because it tests distortion with tones up to +18dB AL it is not suitable for broadcast tests. SEQ2, which only tests up to +8dB AL, is suited to digital broadcast tests, but SEQ6, which uses less sensitive measurement ranges on noise and distortion, and also runs the sweep at -10dB is better suited to FM transmitter paths where pre-emphasis would cause overload at high frequencies on a 0dB sweep. SEQ4 is SEQ3 plus a 20 second noise plot, providing a more thorough test of computers and devices that might have occasional noise clicks. It is useful to remember that these basic sequences can be modified by the subsequent running of certain segments, in particular SEGs (slow sweep)(press SEQ+key1) for more detailed results on speakers in reverberant surroundings, SEGw (wide sweep)(press SEQ+key5) for testing 96k digital system bandwidth, or SEGc (crosstalk) (press SEQ+REL). These are available in stand-alone use, by using the key combinations shown above, and because a master-seg is not run again they replace or add to the segments already run. Where the initial sequence incorporated a normalising master-seg, the added segments are also normalised. Running a master-seg (or resetting) clears existing results.

Notes on Sequences and Segment Limitations

Any combination of segments (up to 6) can be sent as a sequence using the Lin4Win support software running on a PC, with the following provisos:

Only one 'Master-seg' can be sent (usually n) (or m or t)

Only one Sweep seg can be sent (usually u) (or s, or v, or w, or h)

Only one extra plot can be viewed (l or z)

SEGz only works with a sweep (it signals the showing of phase)

SEGt used in place of SEGm adds (azimuth) alignment tones

SEGq runs SEGr too (they share a common text header in results)

Attempting to run LA100 segments alone will usually result in other segments being run automatically. This is because the LA100 requires message text at the beginning and a terminating character at the end. SegT incorporates the header text and also normalises. SegZ (phase) incorporates the terminating character.

Segment letters can be entered in any order, either in the control panel or at the top of the main (results) window (press return to send) – the sending order is fixed (eg nurqcl)

SEGq actually tests distortion at +11.5, +14.5, and +17.5dB rather than the nominal +12, +15 and +18dB quoted for simplicity. This provides a margin of safety to avoid 'just clipping' when equipment is not precisely aligned.

4.4 Viewing Sweep Results on the Unit

Whilst the only way to view a complete set of sequence results is on a personal computer using the Lin4WinXP program, it is possible to examine a frequency response plot on the MiniSonic in a novel way. Simply use the up-down (L-R) keys, with the unit in sequence mode, to move the cursor ('shadowbar') up and down the frequency scale as marked above the LED display. The main bar will indicate the level stored for each frequency. Though simple, this form of display is still very useful, especially when measuring speakers, because sweep results triggered automatically from the microphone signal, and captured in just five-seconds, can be studied at leisure and in silence. Normally the L channel is displayed. Hold SEQ and press R to select right channel display. Press SEQ (or SEQ-L) to return to the left channel.

4.5 Standard Sequences (v3.0 firmware chip)

MS1 Units run all sequences, but only respond to SEGu (sweep)

	Description:	Segs:	Measures:
SEQ0	Line-Up	j	0dB/+8dB line-up/chan ident
SEQ1	'Sweep'	u	sweep 20Hz-20kHz 5 secs
SEQ2	'Broadcast Test'	n,u,r,z	sweep, phase, noise, dist to +8dB
SEQ3	'Digital Test'	n,u,r,q,z	sweep, phase noise, dist to +18dB
SEQ4	'Sound-card Test'	n,u,r,q,l	digital test plus 20s noise plot
SEQ5	'Slow Sweep'	s	sweep 20Hz-20kHz 20 secs
SEQ6	'Tape/FM Test'	m,v,r,z	sweep @ -10dB, & high ranges
SEQ7	'GLITS Test'	g	channel ident and line-up
SEQ8	'Wideband Sweep'	w	sweep 40Hz-40kHz 5 secs
SEQ9	'Headroom plot'	h	level versus level 0dB to +18
SEQ10	'Long Noise plot'	l	noise peak and mean 20 secs
SEQ11	'Distortion segs	r,q	distortion residue -20 to +18dB
SEQ12	'PPM tone bursts'	p	5 'inverse-level' tone-bursts
SEQ13	'Crosstalk'	c	crosstalk at 100Hz 3.15k 10kHz

Special LA100 Sequences: (startup option 9)

SEQ1	'Sweep, Phase, TL'	TUY	sweep 20Hz-20kHz 5 secs
SEQ2	'General'	TRINY	sweep @-10 phase, noise, dist
SEQ3	'Digital Test'	TUDNY	sweep @ 0dB, phase noise, dist
SEQ4	'Broadcast Test'	VRAGNY	sweep etc with 50us de-emphasis

Notes:

SEQ0 only runs at initial switch-on (until a function key is pressed)

To run SEQ5 hold the SEQ key down while pressing key 1

To run SEQ6 hold the SEQ key down while pressing key 2 (etc to SEQ 8)

To run SEQ9 hold the SEQ key down while pressing LEV

To run SEQ10, 11, 12, 13, hold the SEQ key down while pressing NOISE, DIST, PPM, REL

To run LA100 sequences, hold down SEQ while turning on the power.

Any Sequence of segments can be sent using Lin4Win, but see limitations in section 4.3.

4.6 Segments Available (v3.0 firmware)

Name:	Description:	Details: Sequence building segments
SEG n	Master-seg	Test lev/Normalise 1kHz /Noise (-85 to -50dB)/Delay
SEG m	Tape/FM Master-seg	Test lev/Normalise 400Hz/Noise (-60 to -30dB)/Delay/Speed
SEG t	Test-Tape Intro	3.150kHz 8s,10kHz 8s,1kHz 8s, then as SEGm (azimuth)
SEG u	Sweep	20Hz – 20kHz @ 0dB 5 secs
SEG v	Tape Sweep	20Hz – 20kHz @ -10dB 5 secs
SEG w	Wide Sweep	40Hz – 40kHz @ 0dB 5 secs
SEG s	Slow Sweep	20Hz – 20kHz @ 0dB 20 secs
SEG r	Distortion Residue	Dist Res 1kHz @ -20, 0, +8dB
SEG q	Dist Res to +18	Dist Res 1kHz @ 0, +12, +18dB
SEG c	Crosstalk	Crosstalk at 100Hz, 3.15kHz, 10kHz @ 0dB IBA-wtd
SEG h	Headroom Plot	1kHz 0dB to +18dB in 1dB steps 5 sec plot
SEG l	Long Noise Plot	Noise Wtd 468 (-85 to -50dB) L-chan 20 sec plot
Details: Special Purpose Segments:		
SEG p	PPM Tone-burst test	'Inverse Tone Bursts' 1, 1.5, 5, 10, 100ms
SEG y	468-Wtd Tone-bursts	'Inverse Tone Bursts' 1, 1.5, 5, 10, 100ms
SEG b	Tone-bursts	General Tone Bursts 100, 10, 5, 1, 0.5ms @ 0dB
SEG e	Flutter Cal Wobble	Flutter-meter cal wobble (should read 1.1% IEC Wtd)
SEG f	Flutter Test	3.15kHz 20 sec (provisional - not yet recognised)
SEG i	Channel Ident	1kHz 0dB 1 sec, 1kHz -6dB 1 sec, repeating
SEG j	Lindos Lineup	1kHz 0dB L+R 2secs, +8 dB L 2s, +8 L+R 2s repeating
SEG g	'GLITS' test	1kHz -3dB 6s total 1 mute on L, 2 mutes R repeating
SEG z	Phase (FSK only)	Phase Plot (valid only above 1kHz) (Use with u,v,s, or w)
SEG/	Sequence Separator	Use in Lin4Win to separate multiple-sequence generation
SEG<	Repeat (<n optional)	Use in Lin4Win to repeat indefinitely (<3 does 3 repeats)

LA100 Segments:

(* = not currently logged by the MS10)

SEGT	Test Level 1kHz	1kHz @ 0dB (includes 'MS10' start text) 1 sec
SEGV	Test Level 400Hz	400Hz @ 0dB (includes 'MS10' start text) 1 sec
SEGU	Sweep	20Hz – 20kHz @ 0dB 5 secs
SEGR	Tape Sweep	20Hz – 20kHz @ -10dB 5 secs
SEGD*	Distortion (THD)	100Hz, 1kHz, 6.3kHz @ +8dB 6 secs
SEGG*	Distortion 50us	40, 100, 315, 1k, 6k3, 10kHz with 50us de-emphasis 18 secs
SEGI*	Distortion (THD)	100, 1kHz @ +8 and -10dB 8 secs
SEGA*	Crosstalk	40, 100, 315, 1k, 6k3, 10kHz with 50us de-emphasis 6 secs
SEGN	Noise	mute for 8 secs
SEGW*	Wow & Flutter	3.150kHz for 12 secs
SEGY	Phase (and stop)	40, 100, 1k, 6k3, 10k, 15k (includes stop and seg count)

5.0 Advanced Features

5.1 Vernier Precision

Pressing KEY4 and LEVEL together selects VERNIER mode enabling levels to be measured to much higher resolution than the 1dB steps possible with the normal LED display. Only the L channel is displayed (unless R is pressed) and the 'shadowbar' now indicates the fractional reading from +0.5dB to -0.5dB by which the integer reading is in error. The shadowbar is centred at 0 on the bottom scale and can move between -10 (-0.5dB) and +10 (+0.5db) in 0.05dB increments. To adjust a level to 0dB, for example, simply aim for both bars being on zero. Given an input level of, for example, +2.25dB, the main bar will read +2 and the shadowbar +5. Turning up a level gradually will cause the vernier to move smoothly up to +10 and then jump down to -10 repeating for every 1dB of increase. Looking at the MiniSonic's own output in vernier mode, at varying levels, will simply indicate the unit's total fractional dB error for every 1dB step. The vernier indication may become 'noisy' on levels below -6dB. The vernier facility is only available in LEVEL mode: to cancel it just press LEVEL (or any other function key).

5.2 Relative Levels

A REFERENCE level is stored in the unit at all times, and this is set to 0dB at switch-on. Pressing dBu/REL makes all readings read relative to the reference level, and pressing it again returns to absolute reading. The red LED above the button flashes when relative readings are being made.

5.3 Normalising

Holding down the dBu/REL key for at least one second, while in LEVEL mode stores the current input level as the Reference Level (and toggles to relative reading as shown by the flashing indicator). The reading should therefore jump to 0dB: if it doesn't (as occasionally happens for big changes), just press and hold again. All subsequent readings, in all modes, may be made either absolute or relative to this stored level simply by toggling dBu/REL on or off. This is most useful for relative noise readings at non-standard alignment levels. For example: suppose that a CD player, playing the alignment-level track of the Lindos test CD2 reads -2dB on LEVEL. Press and hold dBu/REL and the reading changes to 0. Press NOISE, and the reading is -15, which now represents -65dB noise *relative* (indicator flashing). Press dBu/REL and the reading changes to -67dBu, which is the absolute noise level. A quick way to read relative noise is simply to press DIST, wait a second, and then press NOISE, because DIST sets 1kHz and normalises prior to reading distortion, and leaves relative reading set (indicator flashing) unless it is cancelled by pressing dBu/REL.

5.4 Range Changing

On LEVEL, NOISE and DIST functions 10dB of either attenuation or gain can be switched in, independently of any normalisation already applied, giving two new ranges even on relative readings. Holding LEVEL and pressing the < key increases the sensitivity by 10dB. Similarly the > key decreases the sensitivity by 10dB. Holding NOISE works similarly for noise readings, but when holding down DIST it is necessary to wait a second for normalisation to complete before pressing < or > to change range. Pressing LEVEL or NOISE or DIST restores the default range for each function.

5.5 Manual Reference Setting

The gain adjustment facility described under PPM actually works by changing the reference level. It therefore provides a way of setting the reference level in 1dB steps. This can be used as a sort of range changing facility (though note that for remote control purposes reference level and range are actually independent parameters that are summed in the unit to control the applied gain). The range of level and noise measurements can be extended using this facility. For example, hold down PPM and use the up-down keys to set the cursor to +20dB (it actually wraps to -10). Now select NOISE and the readings will have increased by 20dB, permitting reading down to -90dB.

5.6 Normalising In Sequence Mode

It is usually advisable to include a 'master-seg' (n or m) in every sequence as this automatically causes a reference level to be saved, and sets relative-reading (as shown by the commencement of flashing of the dBu/REL indicator). This ensures that noise is measured relative to Alignment Level, and also that distortion segments operate within their optimal signal level range, regardless of the actual level coming out of the equipment under test, avoiding the possibility of front-end overload. Only the Test Level results indicate the true level of output from the equipment before normalisation. Distortion Residue is relative to the individual tone used, however, not Alignment Level, so -40dB on the +18dB tone means 40dB below +18dB, or 1% in traditional terms.

If sweep or noise segments are run without a master-seg, then the results will be absolute in dBu. This provides one way of altering the amount of headroom available on sweep graphs. These normally limit at +10 and -22dB which is plenty for normal use when testing nominally flat equipment. It may not be enough though when testing filters or equalisers, in which case running the sweep at, say, -5dB (do a reset first to cancel existing master-segs) will result in a graph with 15dB of 'headroom'. Alternatively, it is possible to run the sweep at normal level, but manually set the reference level by holding PPM and using the < and > keys. With the REL indicator flashing, press SEQ and run segments in the normal way and they will be normalised to the manually

set reference level, provided that no master-seg is run. Running Distortion Residue segments without a master-seg is not recommended.

Once a master-seg (n or m) has been run, the reference level it acquired is applied to all subsequent segments, as indicated by the flashing REL indicator. If extra segments are then run, such as an alternative sweep or a noise plot, then normalisation will also be applied to these. Running a master-seg resets the reference level and clears the existing results list. Resetting the unit also clears the results list, allowing segments to be run without normalising if desired.

5.7 Tone-burst Testing of PPM's

SEQ 12 runs SEGp which is designed to test the dynamic characteristics of PPM's (Peak Programme Meters). It does this by generating five bursts of high frequency tones, of different durations and at amplitudes designed to cause a correctly responding PPM to peak to 0dB on each of them. For fuller details see Section 11.3.

5.8 Tone-burst Testing to ITU (CCIR)-468

SEgy (available using Lin4Win) works in exactly the same way as the PPM test, but is designed to test Noise Meter dynamics to ITU (CCIR) Recommendation 468. Again, each of the tone-bursts is designed to give a peak reading of 0dB on a properly working meter, but this time the level is set for a target reading of -50dBu (a typical level, and the standard range set in the MiniSonic in stand-alone operation). Note that the levels have been calculated to take account of the ITU-468 weighting filter response at the 5kHz burst frequency, so the test gives a good measure of overall accuracy and freedom from overload limiting in the most relevant region of the weighting curve. Though of little use to the general user, this test is appropriate to the Lindos aim of increasing understanding and adoption of the 468-Weighted Quasi-Peak method of noise and distortion residue measurement. Tone-bursts are 1, 5, 10, 50, 100ms @ -46.3, -53.7, -55.3, -57.1, -58.4dB respectively (to nearest 0.5dB), with 2.25s delays in between. All should hit 0dB on the scale (-50dBu).

5.9 Time-Delay (Path Latency)

Long signal paths, such as satellite links and long landlines, can introduce a time delay of 100ms or more, enough to make conversation difficult. The MS10 measures the delay on any return path by timing its FSK, and this is listed in milliseconds as 'DELMs' on Lin4Win results whenever a master-seg (m or n) is run, under the TL heading. Delays of 1ms to 10secs can be measured to an accuracy of $\pm 0.05\% \pm 1\text{ms}$. Codecs (MPEG etc) also introduce delays, which can be measured to aid video synchronisation.

6.0 Using Lin4WinXP Support Software

Although preceding sections have described the detailed ways in which the MS10 can be used as a stand-alone unit, which can be very valuable, its full potential only becomes apparent when connected to a PC running Windows (preferably XP but all earlier versions back to WIN95, including NT, work fine), and our Lin4Win support software, which is free to MiniSonic users.

Installing Lin4WinXP

To install from CD simply click on the CD drive and then double-click on the 'setup.exe' Windows Icon in the usual way. Alternatively, download the latest version (free) from www.lindos.co.uk

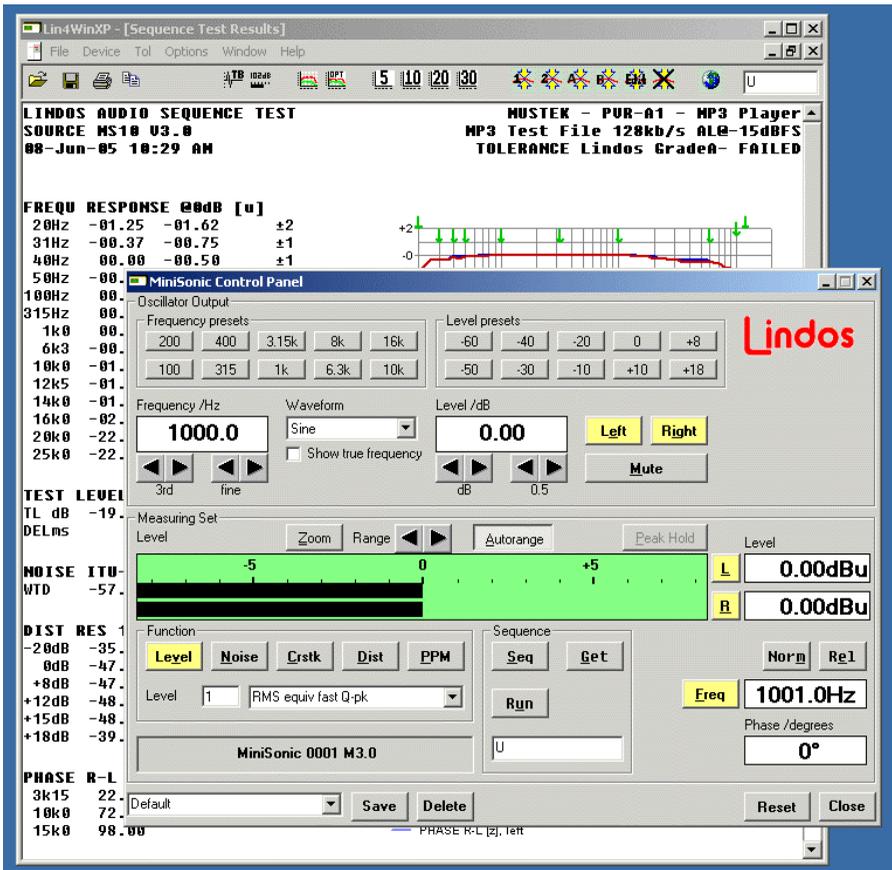

Running Lin4WinXP

You can click on 'Start' (bottom left), go to 'programs' and double-click on 'Lin4WinXP'. A better way is to create a 'shortcut' to Lin4Win on the desktop, in the usual way, and then just double click on it whenever you want to run the program. One way to create a shortcut is to click on 'start' and then follow across 'all programs' and find Lin4WinXP. Right click on this and then click on 'create shortcut'. This will add a shortcut icon to the list, which you should drag-and-drop onto the desktop.

On launching, the window that appears says 'Lin4Win' (and the version number) momentarily. The control panel will then normally open along with the main window (if not, click 'Options' and then 'MiniSonic Configuration'). Connect the MiniSonic to an RS232 COM port on the PC, if you have not already done so, (or use a USB to RS232 adaptor), and wait for the status window at the bottom left to display 'MiniSonic 0001 M3.0' indicating that communication is established. If this does not happen, click 'Options' at the top of the main window, and then click 'comms settings'. Select the appropriate COM port (1 to 4) and click OK and you should see the status window change to indicate lock-on. Trying each COM port in turn is permissible; there is no need to quit and restart.

6.1 The Control Panel

The control panel reflects the state of the MiniSonic unit in real time. A complete set of current values and settings is sent by the unit 110 times every second over the RS232 connection, using a self-synchronising binary format that we call 'SynkLink'; this ensures flicker-free readout. The MiniSonic is controlled by Remote Commands (see Appendix E) sent in the other direction when a button is pressed.

Control panel operation is mostly intuitive, the main difference from stand-alone use being that instead of a fixed range being set, autoranging is operational, with the figures above the bar graph changing to reflect the range in use. To fix the range, click on the Autorange button, or just use the up-down buttons to set the desired range. The buttons and indicators on the MS10 panel are still functional, so for many purposes it may be convenient to use the PC as just a display, with no need for a keyboard or mouse; selecting and running sequences, for example, from the unit itself.

6.2 Level Measurement

Range changing extends level measurement with five 'real' ranges centred on -30dB to +20dB. The bargraph display itself continues to alter its scale below -30 extending useful readings to beyond -50dB. Note that 'real' range changes occur inside the MiniSonic, and therefore affects its bar graph display, which, though still reading correctly, needs to be interpreted with reference to the range in use. L or R channel selection, though available from the unit itself,

does not function from the Lin4WinXP control panel. There is, of course, no need for it with a full two-channel display.

6.3 Frequency and Phase Measurement

Frequency and Phase only work in LEVEL mode, when the **FREQ** button is illuminated. Normally they are off because low frequency measurements necessitate brief interruption of normal operation. Click **FREQ** to turn frequency and phase measurements on. The **LEV** indicator on the unit will be seen to flash every time a frequency measurement is made, and the measurement rate (normally once a second) can be changed by going to 'Option' and 'Minisonic Configuration'. This menu also allows the **AUTO-TURNOFF** time to be set, extending the 4 minutes of the MiniSonic itself. Frequency measurements have a resolution of 1Hz and are accurate to 0.01%. Phase measurements have a resolution of 2 degrees extending from –180 to +180 with the L channel considered the reference so that, for example, –20 means that the R channel lags the L channel by 20 degrees.

6.4 Noise

Click the **Noise** key to measure noise, ITU-468 Weighted Quasi-Peak (referred to elsewhere as 468-Wtd for brevity). The oscillator mutes automatically and Autorange operates using 'real' ranges from -60dB to +20dB. The bargraph continues to alter its scale below –60, extending useful readings to beyond –80dB. Only one bar and one digital level display are functional. Click **L** or **R** to change channel.

6.5 Crosstalk

Click **Crstk** to measure crosstalk, 468-wtd, at any frequency or level. This operates as for **NOISE**, with automatic muting of the oscillator on the channel being measured. Click **L** and **R** to change the measurement channel; the oscillator will change to drive the other channel at the displayed level and frequency, which can be changed. Note the comments in section 2.7 regarding the weighting curve and the desirability of running the crosstalk segment, which gives results to a preferred (IBA) weighting curve.

6.6 Distortion

Click **Dist** to measure Relative Distortion Residue, 468-Wtd. As in manual operation, the unit first normalises the level, but it then autoranges on the distortion residue. Readings are relative, unless **REL** is turned off. Normalisation ensures that front-end overload does not occur for all levels up to +18dBu. Autoranging operates using 'real' ranges down to -50dB (extra gain in the unit), with automatic scaling of the bar graph extending useful measurement down to around –80dB (but refer to Section 18.3 for reservations regarding drift and notch depth affecting very low readings).

6.7 PPM

Press PPM to measure programme levels with PPM characteristics (IEC type IIb (UK/BBC standard). This function differs from others in that autorange is deselected (though it can be turned on). This is because PPM mode will usually be used as a programme level display and range changing would only be confusing. Note that an output is available from the unit (Line Out) at which 0dB on the scale always corresponds to 0dB out, ie for use into systems with 0dBu Alignment Level. Input sensitivity, however, can be adjusted by holding down PPM on the unit itself and using the up-down keys (L and R) on the unit. This gain control facility is not available from Lin4WinXP, except by clicking NORM on a test tone at the desired input alignment level. The rapid update rate to the computer over 'SynkLink' (our name for a continuous RS232 binary data stream at 110 readings/sec) provides a smooth, jump-free bargraph display with true PPM dynamics on the screen (other PC displays of programme meters are all too often jumpy and not to specification!)

6.8 Relative Levels

These work just as on the unit itself, and use the reference level stored in the unit. REL toggles the unit between absolute and relative reading when reading level, noise, or crosstalk (button turns yellow). The difference is that a separate NORM button can be clicked (usually while in Level mode) to capture the current reading as reference level (instead of holding down the REL key).

6.9 Zoom

Clicking ZOOM toggles the bar graph between normal and expanded form. When expanded, the entire scale represents just over +/-1dB, ideal for examining small signal fluctuations. In ZOOM mode the range changing operates in 1dB steps permitting any desired range to be selected. Note that the range selected will also apply within the unit itself, and be reflected in its bar graph display, though the expanded scale will not apply on the unit.

7.0 Oscillator Setting in Lin4Win

7.1 Frequency

Just click the up-down buttons, which repeat when held. Note that either the true synthesised frequency or the nominal 1/3 octave value can be displayed, from 4Hz to 40kHz. Square waves (currently 1kHz, 5kHz or 10kHz only) can be selected from the WAVEFORM menu. Note that square waves are generated with the same *peak* level as a corresponding sine wave (not the same rms). This results in the same reading when measured (Quasi-Pk) on a

MiniSonic, and is also convenient in testing.

7.2 Level

Just click the up-down buttons. Note that 0.5dB, as well as 1dB steps are available, from -90 to +19dBu.

7.3 Presets and Settings Files

These can be used to set frequencies and levels instantly. Although each defaults to a set of commonly used values, any preset button can be reprogrammed to the current oscillator setting by clicking and holding on it for one second or more (or shift-click). A panel setup can be saved by typing a name into the bottom left hand window, and then clicking the SAVE button next to it. This saves the presets and also any user sequences that have been defined. Any stored settings file can be applied subsequently by clicking on the menu arrow and selecting from the list. To delete a settings file, select it and then click on DELETE. At start-up the last settings file used is applied.

7.4 Mute and Channel Selection

The MUTE L AND R buttons for the oscillator output interact in a clever way. Mute toggles between both channels off and whatever the previous state was. L and R each toggle their own channel on or off. This arrangement will be found most convenient in testing, and the buttons always turn yellow to indicate clearly when a channel is turned on.

7.5 Tone-bursts

To generate tone-bursts at any frequency and level, with durations from 1 to 255ms, click on TB at the top of the Results Window and a small 'Tone-burst' control panel should appear. Enter the required Frequency, Duration and Level into the appropriate boxes and click on Tone-burst or press Enter (or Return). The first click mutes, then subsequent clicks generate the burst. Tone-bursts begin and end at a zero crossing of the waveform, so for the correct length it is desirable to choose a frequency that fits a whole number of cycles into the duration. Note that tone burst generation blocks normal processing momentarily in the MiniSonic, so that attempts to measure the unit's own PPM response will not give correct results. Tone bursts are useful for testing level-compressors and programme level indicators as well as for studying reverberation in listening rooms, and testing for high-level compression on speakers without burning them out.

8.0 Sequence Testing with Lin4Win

8.1 Running A Sequence

Sequence testing in conjunction with Lin4Win is where the MiniSonic really comes into its own for routine quality testing, producing a complete set of test results with speed and convenience unmatched by any other equipment. Many users will never need to use the unit in any other way: in fact, they may find that just running SEQ3 is all they need ever do! Other sequences are tailored to various applications, and may take longer, but SEQ3 will produce a revealing set of two-channel results from most equipment in just 20 seconds.

To run a sequence, click RUN (control panel) and the segments shown in the text-box underneath will run (indicated by the SEQ light flashing.) These segments can be entered by clicking the mouse-cursor on the box and typing, or a set Sequence can be called up by selecting from the drop-down menu in the sequence box to the left. An alternative entry box is provided at the top of the main (results) window purely for convenience. When the sequence is complete the flashing stops and GET lights up; and within two seconds the results should appear in the main window automatically. As an alternative to clicking RUN just enter the segments and press Enter (or Return). As with stand-alone operation, the sequence is run relative to the current oscillator level displayed, and measured relative to the stored reference level if REL is lit during the running (see section 5.6 for a full explanation). To save a user sequence enter the segments as usual, enter a name (over 'user sequence') in the sequence box, click the 'SEQ' button. 'Save' will save user sequences. Clear the segments and click SEQ to delete a user defined sequence.

8.2 Downloading and Interpreting Results

Though this is automatic whenever a sequence is run, or received, it is of course possible to download the stored results from any MiniSonic unit at any time by simply clicking GET. This is useful when a sequence has been run and the results stored in the MiniSonic to be carried back to the PC for viewing, for example when testing a loudspeaker in another room. Results can be downloaded from the unit again and again, unless they are overwritten by running a new sequence or cleared by turning off or by resetting.

A typical results page (see section 9.1) begins with a title, date and time (inserted by the PC), the latter being useful as a reference code when a number of similar results are being compared or put into order. A Header on the right hand side can be entered by the user, and will usually contain the equipment make and type along with details of the settings or test conditions.

Then come the listings of results on the left, with corresponding graphical representations on the right. These graphs can each be viewed individually in a separate window, on a larger scale, and with numerical cursor readout using the Graph Viewer. They can also have their appearance altered in terms of

height, width, scaling, normalising and colours using Graph Options. The bar chart representation of Distortion Residue is particularly interesting as it contains a lot of information designed to allow at-a-glance assessment of performance. The first bar represents the Noise level, followed by bars for relative Distortion Residue at up to six levels. The first of these (at -20dB) is often the most revealing. In the absence of significant distortion it will indicate a figure 20dB worse than the noise bar (because it is showing noise relative to the -20dB level and not alignment level) but crossover distortion (in amplifiers), quantising errors (in digital convertors), and modulation noise (on tape) will all show as further worsening. Manufacturers are keen to produce very low figures for distortion measured at MOL (maximum output level) or FS (full scale), but in practice these are of little relevance compared to performance at -20dB AL (typically -46dB on CD) where low relative levels are harder to achieve and defects are more likely to be heard.

8.3 Saving and Viewing Results files

To save a results file go to 'File' and then 'Save as' in the normal way. Select the Folder you wish to save to, and give a name to your file. You will probably want to create a 'Results' folder and then folders for categories such as 'CD Player, PC Card, etc within that. Some example results files are supplied by Lindos (look in Program files, Lin4Win) to start you off. To open a saved Results file go to 'File' and then 'Open' in the normal way. Quicker access is obtained by using the shortcut keys CTRL+O to open or CTRL+S to save. Note also that you can drag-and-drop files onto the results window.

8.4 The Graph Viewer

To view any graph in more detail just double-click on it and the Graph Viewer will open in a new window. Click anywhere in this window to move the cursor, which allows the x and y values to be read off accurately.

8.5 Graph Options

Click on the icon marked 'OPT' at the top of the Results window (or use 'Options', Graph Options'), and a new window will open allowing various features of each graph to be changed. These include the size and scale, colour, and grading zone indication. Tabs along the top of this window allow each graph type to be customised independently. Frequency responses can be 'Absolute' or normalised relative to 1kHz , 400Hz , etc. 'SPL' adds 100 to the absolute values, to show Sound Pressure Level when Lindos calibrated mics are used. Normalising works independently on both channels, and also affects the results listing, to permit tolerance testing. A series of buttons marked 5,10,20,30 along the top of the Results window allow quick-scaling of graphs. Click on a graph first to select it, and then on one of these buttons to change its vertical scale. The Dist-Res bar-chart uses fixed scaling to make equipment comparisons easier.

8.6 Adding Page Headers and Commentary

The headings on the left-hand side of the results page relate to the source, and the date and time of download to the PC. The Results Header on the top right-hand side can be edited by the user – just double-click on it to open the 'Results Format' window (or click on 'Options' then 'Results Format'). Four boxes are available labelled 'Equipment Make', 'Model', 'Type', and 'Settings'. Although these can be used freely to contain any text, users are urged to fill them in as indicated, and in particular to select the 'Equipment Type' from the drop-down menu where possible. This is because our online Test Sheet Database organises uploaded files automatically using these entries (see Section 8.7). The first three entry boxes are combined onto the first line of Results Header, with the test conditions on the second line. A typical entry might read '*Lindos - LSC24 - AD/DA Converter*' on the first line, followed by '*44.1kHz 16bit Noise-Shaped*'.

A further box in the Headings window is labelled 'Comments' and this can hold a large paragraph of text, which appears below the column of figures on the left hand side of the Results Sheet. It is suggested that this be used to make comments on any faults, good features, or peculiarities that other users might be interested in. All Headers, graph options, tolerances, and commentary are saved with the file, but can be edited later if desired.

8.7 The Lindos Test Sheet Database

Lindos Electronics has set up a database of equipment test results on the Internet (www.lindos.co.uk), to which any MiniSonic user can upload results files. With your help, Lindos aims to provide free at-a-glance comparisons of audio equipment quality, using methods that are subjectively valid regardless of the nature of the equipment under test. The site is for all equipment that uses audio; professional or consumer, including video equipment, MP3 players, camcorders etc. Having chosen the sequence that you think most appropriate, and obtained a results page in Lin4Win that you think may be of interest to others, make sure that you enter the Equipment Type and details (see paragraph above) plus any comments that you think appropriate. You will probably want to save the results (Ctrl-S). Then just click on 'Publish to Web' (Globe icon at top RHS). You can view existing database entries in your browser by clicking on 'Open Database'. To upload a results file, you will need to open an account. Then click on 'Publish' and your file will be uploaded, listed in the index (searchable by equipment type, make etc) and immediately viewable by all (as HTML files). We have chosen to convert results files to HTML (rather than PDF) for faster viewing. The automatic inclusion of relevant keyword and description metatags means that they quickly achieve high rating in search engines like Google.

This is about revealing the truth, not fudging the figures, but while we wish to show up deficiencies, and hence influence sales of equipment, for better or

worse, it is important to be fair. Initial comments should therefore be constructive, aimed at helping the manufacturer as well as the user, and not gratuitously offensive. Lindos will remove any pages it considers unsuitable. Users cannot edit or remove pages that they did not create, unless they have special 'administrator' status.

Use SEQ3 for most equipment, or SEQ4 if intermittent noise clicks could be present (computer sound cards!) Use SEQ6 for cassette decks and lower quality devices where noise or distortion exceed the upper limit of SEQ3.

8.8 Tolerance Testing

To try out tolerance testing, just click on one of the tolerance icons labelled A or B (two arrows) at the top of the Results window. This will instantly add a heading such as 'TOLERANCE Lindos GradeA PASSED' and a column of tolerance limits next to the results listings. If the heading says 'FAILED' then an asterisk will appear by each failed result. To remove the tolerance indications, click on the icon with a cross through it. Whilst the Grade A and Grade B buttons are not normally alterable, two more tolerance buttons, labelled 1 and 2, are for use with user-chosen tolerances (though as supplied they bring up Grades A+ and A-). To alter these, click on the 'Options' and choose the files you wish to associate with buttons 1 and 2. An alternative way of applying tolerance files, useful when trying out several, is to drag-and-drop them directly onto the results window. Results files store any tolerance file applied at the time of saving, and this is automatically applied on opening. To turn the tolerance indications off just click on the tolerance icon with a cross through it. If a results file with tolerances applied is published to the Web, the resulting HTML page will show applied tolerances.

The tolerance editing button, alongside the 'no tolerance' button, opens a tolerance editing window, allowing the currently applied tolerances to be changed. To create a new tolerance file, just load an existing one, such as A or B, and then open the tolerance editor. Save the file under a new name (to avoid saving over the existing file) and then you can experiment with changing the various limits, and clicking 'Apply' to try them out, before saving the results, or the tolerance, or both. Attempting to save over the Grade A and B tolerance files will not alter them.

Tolerance files are simple text listings of the form shown below where each segment character is followed by limits for each of its listed values, separated by commas. The limits can take a variety of forms such as ± 1 , or $+1-2$, or just -40 (see example below). Leaving out the value before a comma implies a repeated tolerance, and a question mark means no tolerance to be applied. Where a line begins with two or more segment letters (eg uvs) the tolerance list that follows is applied to these segments. Tolerances refer, in turn, to each line in the list of values that follows a character in square brackets, such as [u], in the results sheet. Usually these signify the segment that produced the

results, but note that [t] (test level) and [e] (speed error) are 'notional' segments only – labels used to permit tolerances to be applied independently to results that are actually part of another segment (in this case n or m).

Changes only take effect when you click the 'Apply' button. Click on 'File' and then 'Save' when you are ready to save

"Lindos GradeA"

w \pm 1, \pm 2,? Means \pm 1 then \pm 2 then no further tol

uvs \pm 2, \pm 1,,,,,,,,,,,,, \pm 2,? \pm 2, then \pm 1 for 11 values, then \pm 2

t \pm 1<1,<100? Level \pm 1, difference <1, delay <100

nm-60 Means noise <-60

r-40,-45,-45,-45,-45,-45?

c-40,-40,?

Several tolerance files are supplied with Lin4Win, including our 'Grade A++' 'Grade A+', 'Grade A', 'GradeA-', 'Grade B, (see below for details) and 'MS10 Self-Test'. They will be found in the 'Lin4Win' program directory (ending .tol), as will various example results files (ending .res). The GradeA and GradeB icons always access their files from this directory, but it is recommended that a 'Results' directory be created in 'My Documents'. Start by copying the Lindos supplied 'Results' directory to this new location, and then add your own files as required, using sub-directories for categories ('Tape','MP3', 'Tolerances' etc) as you feel the need.

8.9 The Lindos Quality Grading Scheme

The Distortion Residue graphs are marked with quality grading zones (which can be turned off in Graph Options) marked 'Fails Lindos Grade A', and 'Fails Lindos Grade B', and these are part of a Quality Grading System designed on the basis of our own listening tests as follows:

'**Lindos Grade A**' indicates a level of quality that produces no perceptible degradation whatsoever for critical listeners in 'blind' A-B testing under the very best listening conditions. It is close to what would be expected from good 'CD quality', and demands a flat 20Hz to 20kHz response.

'**Lindos Grade A+**' requires noise and distortion figures to be 5dB lower, and response errors to be halved. Two A+ systems cascaded, or four A++ systems, can be assumed to meet Grade A or better.

'**Lindos Grade A-**' is a slightly relaxed version of Grade A, demanding a flat response only to 14kHz for use in testing FM broadcasts and MP3 players which commonly cut off above 15kHz. This is better than commonly supposed, and even people able to hear 20kHz cannot generally detect the insertion of a 15kHz filter.

‘Lindos Grade B’ represents a level of quality that most people most of the time would find ‘near perfect’. The best compact cassette decks will meet this grade, using Dolby C or possibly Dolby B and though cassette tape may be regarded with derision these days it is a fact that, for many years, cassette manufacturers strove to achieve total transparency with impressive results.

This grading system will of course be controversial, but it’s a start, which in our opinion is long overdue. Lindos Electronics has developed a unit called ‘the CORRUPTOR’ which allows any level of noise, crossover distortion, clipping, bandwidth-limiting etc to be switched in or out of an analog signal path, and anyone who thinks that the levels of distortion set by the grade zones are excessive would, we think, be surprised if they actually did listening tests with such a unit! Of course, there has to be the proviso that we are only testing the main parameters, and that loudspeakers in particular will sound different depending on their ‘coloration’ caused by ringing, and also on their off-axis radiation characteristics. Tape machines will also be compromised by flutter unless this is below about 0.05% (only very rarely achieved on cassette). Then of course there are the modern digital codec (Coder-Decoder) standards MPEG2, MP3, AAC, ADAT etc for compressing audio into a variety of lower ‘bit-rates’. These use perceptual coding which throws away information that is assumed to be ‘masked’ by components that are adjacent in frequency and time, potentially introducing a very different form of distortion: a loss as well as an addition. They are best treated as a separate factor in the process of reproduction, to be improved on by research, and a feature of the source format not related to equipment defects. A system free from the ‘traditional’ distortions quantified by the MiniSonic will allow any source to sound its best. A system that fails to pass Lindos Grade A cannot be assumed to be ‘transparent’ on the best source material.

The -20dB Distortion Residue figure is often the critical factor on a Lindos test sheet – whether on analog tape, where it reveals not just distortion but modulation noise, on digital systems where it is limited by the noise floor or by quantising errors, or on power amplifiers, where crossover distortion once gave all transistor amplifiers a bad name. Very low levels of distortion on high-level signals are simply not audible, and not necessary.

In any real audio chain of course there will be many items of equipment, and to get the best from the weakest links it is sensible to ensure that the strongest links add negligible defects. Mixers, power amps, control units, and other items of equipment that can easily be made to exceed grade A might therefore be expected to achieve an A+ or A++ rating. The ways in which distortions add up in an audio chain are interesting to consider. Noise contributions measured rms add as power, so two cascaded items each with a noise level of, for example, would measure -57dB rms and four would measure -54dB (3dB worse every time two equal contributions are added). Peak measurements however, add as voltage, the highest peaks adding together, though only coinciding occasionally, so that two sources of -60dB cascaded

could measure -54dB pk (6dB worse for every doubling). Adding noise sources changes the PDF (probability distribution function) – how often the signal hits each level - not to be confused with its spectral density.

Two sources of 'white' noise can have different PDFs and sound different! So when many sources of noise are added together the result is not just more of the same; and the subjective effect is not easy to predict. In reality, two similar noise sources cascaded may sound more than 3dB worse, but will not sound 6dB worse, and quasi-pk measurements are effective in assessing how the result will sound. The effect of altered PDF is actually very noticeable when working with video, where high peaks stand out like a sore thumb to the eye; which is why copied videotapes tend to look worse than might be expected, that is, more than 3dB worse.

Non-linear distortion is more complicated still, because two distortions can actually cancel each other out, or, if they are of the same type, add as voltages (6dB worsening)! Using the Dist Residue method it is fair to assume a similar rule as for noise, somewhere between 3 and 6dB of worsening. The same is true for frequency response, but here there is a special case; almost every piece of equipment ever made is down at low frequencies (LF) – never up! So string together a CD player that is -3dB at 30Hz, a control unit that is also -3dB , and a speaker that is -6dB at 30Hz (actually quite hard to achieve) and the result is . . . very little bass!

To sum up, it is fair to assume that two pieces of equipment meeting Grade A+, or at least four meeting grade A++ can be cascaded and still achieve at least Grade A overall. Beware the effect of multiple LF roll-offs, which add directly and cause loss of initial 'slam' on bass drums. Though partly attributable to loss of low frequencies, this may also be the result of phase shift causing the initial pressure wave to reverse too soon.

9.0 Digital Equipment Testing

A selection Lindos test Segments, and sequences, is available as MP3 or WAV files for download from the www.lindos.co.uk website. These can of course be put to CD or uploaded to media players to test soundcards etc.

Although the MiniSonic is, at first sight, an analog test set, it is capable of testing the best 24-bit digital systems for noise and distortion down to the lowest achievable levels. With a maximum output signal level of +19dBu and an input residual noise level of -90dBu (468-Wtd) it has around 10dB more 'dynamic range' than the best digital systems, and some 30dB more than most 16-bit systems! This demonstrates a major advantage of using an analog test set: it can test in both domains, to the highest standards. It might be thought that a digital test system would outperform analog, but this is simply not so. No digital system capable of +18dBu output is likely to achieve a noise level much below -80dBu (468-Wtd), so to compete in the analog domain it needs adjustable analog gain switching. The figures often quoted for digital systems, of 110dB or more of 'dynamic range', have to be taken with a pinch of salt; they are usually measured unweighted or A-Wtd rms, and relative to full-scale, and so are not directly comparable with our subjectively valid measurements.

To test a purely digital piece of equipment of course, it is necessary to convert the output to analog using a digital convertor, and Lindos supply several convertors for this purpose. There is a lot to be said for the concept of regarding analog as the fundamental domain, and conversion as part of the set-up under test, for several reasons. Firstly, most equipment has analog inputs and outputs anyway. Then, the inputs and outputs may be at different sample and bit rates, with different alignment levels; especially when a complete path in a broadcast or studio environment is being tested, so it makes sense to choose and set up each convertor accordingly. And, of course, all real signal chains start and end as analog, at the microphone and loudspeaker which are usually the weakest links in the chain. A purely digital test set is therefore restricted in what it can test. In many situations where a digital input is required, a test CD or digital test file can be the source. In others, a CD player with suitable digital output can provide a convenient source of sequence tests when used with a Lindos Test CD (CD2).

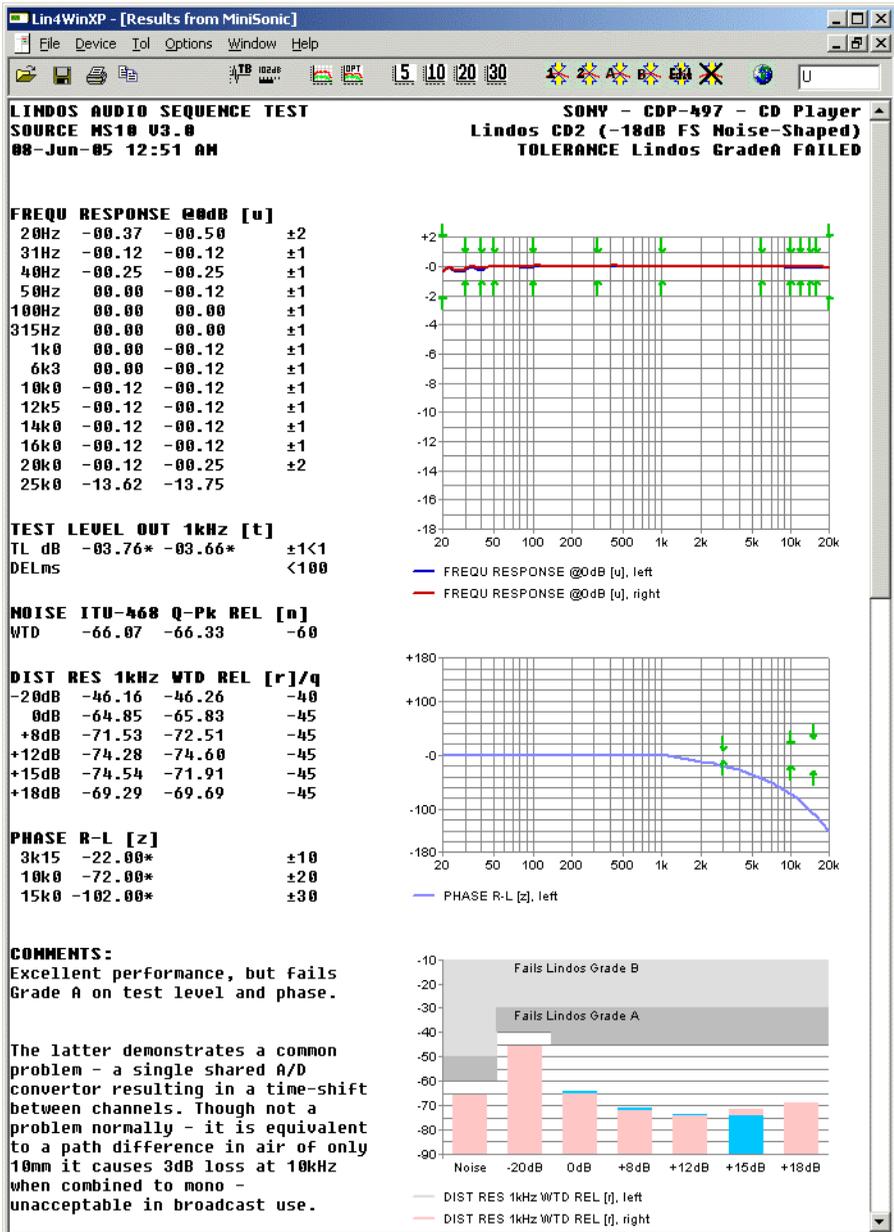

Figure 1 A Typical Results Sheet for a good CD Player

9.1 Testing CD Players

CD2, a Lindos Test CD, available from Lindos, or as a download at www.lindos.co.uk (use a 'Music' CD-R when making a test CD – see later comments), has been designed to facilitate the rapid sequence testing of CD players. Unlike most test CD's, this one has all levels referenced to Alignment Level, which means that, unlike most test CD's, it does not immediately burn out your speakers or deafen you with unrealistic levels! By measuring noise relative to Alignment Level, meaningful figures are obtained, though both low and high level bands up to FS are provided for further distortion checks. A variety of sequences is provided, along with tones and silence (with or without dither or noise-shaping).

Just connect the MS10 using appropriate Lindos leads, and press SEQ. Then play Track 13 which will generate SEQ3 at -18dB FS alignment level, and wait for the sequence to finish (by listening, or by looking for the next track to commence). Track 4 has been allocated deliberately as Mute, so that there is no rush to pause the player. When playing other tracks it may be necessary to pause fairly quickly, or use the program facility on the player, to avoid FSK-triggering by the next sequence.

A typical results page (see Fig 1) should show a Noise level of -65dB or less. All sequence tracks on CD2 use noise-shaping rather than other forms of dither to achieve the lowest residual noise floor, allowing very good players to be distinguished. The $+18\text{dB}$ Dist Residue should be reasonably low (-50dB or less). The 'Test Level' figures in the results, show the deviation of output level from the assumed UniSon standard. Consumer players typically have a specified Full-Scale output level of 2V FS ($+8.23\text{dBu}$) which corresponds to $+14.23\text{dB}$ relative to the Unison alignment level. An Alignment Level tone 18dB below this therefore gives rise to a Test Level of -3.68dB (14.32-18).

All tracks are duplicated at an alternative Alignment level of -15dB FS . While -18dB FS is the main recommended EBU Alignment Level for studio recordings (other EBU recommended levels are -12 and -24), there is a case for using Track 3 (-15dB FS), rather than 13, especially when testing consumer CD players, for two reasons. Firstly, it results in an output level close to the UniSon standard (-6dBu) on typical consumer CD players. Secondly, there is actually no recommended headroom figure for CDs and in recent years recorded levels have been pushed ever higher in a rather stupid and futile attempt to make 'pop' recordings in particular sound louder than the competition! While early CDs tended towards having peak levels 18dB above 'typical' level, the worst recent pop recordings spend most of the time within 6dB of FS, so 15dB is currently a good working figure to assume. Thirdly, most items of consumer equipment; camcorders, set top boxes, and PC cards especially, fall far short of true 16-bit performance, so trading a little headroom for less noise, by assuming an alignment level 15dB below FS for all 'consumer' equipment is perhaps a good idea. If test files aligned at -15dB FS

are used, the +18dB Distortion Residue result is not valid, since the tone is already clipped in the file.

CD-R's 'burnt' on a PC often fail to play at all on standard CD players. This is because of the different nature and size of the 'pits' made on a CD-R from those on mass-produced (injection moulded) CD's. The laser drives in PC's are set up differently, and have no problem reading either type of CD, but we have found that even top quality CD-R's have poor compatibility with many music-only CD players. Usually, the problem is just a high error rate, which the player is designed to conceal as far as possible, so a CD may sound fine one day and then stop playing the next, because the error rate was only just being coped with. To test for errors, just play track 4 of the test CD (mute), press NOISE and listen for clicks, which will often be heard at a rate of several a second. A good CD will not have any clicks at all – they occur when the powerful error correction in the player, which relies on redundant information, cannot reconstruct the waveform perfectly and so resorts to 'interpolation' in an attempt to mask the error. Interpolation is the reason why the clicks are usually at a low level and not heard on music. Copying the test CD onto a particular brand of CD-R is therefore a good way of assessing its suitability for music recording, and keeping a CD-R that has a high error rate is a good way of testing how tolerant a CD player is of pit variations. We currently use Maxell Music CD-R's, which claim to use a special dye, finding that they really do work, giving no errors at all on a player that consistently fails to play standard top quality TDK CD-R's. This is not to say that the TDK CD-R's are inferior to Maxell of course – they may well be better for PC use, but there is a compatibility problem with some players. Do not assume that all 'music' CD-R's will solve this problem. Unless they specifically claim to improve the laser reading on music players, including the word 'Music' may just be an advertising ploy. It can also mean that the CD has a special pre-recorded code or pilot track that is needed by certain stand-alone CD recorders, so read the label carefully. Running SEGI (long noise plot) is a good way of testing for errors, which will show clearly as spikes. Errors are also audible as clicks when measuring distortion residue.

9.2 Testing Computer Sound Cards

Sound cards, or onboard computer sound outputs present special problems because, in general, they provide a multitude of 'frills', such as level, tone, and balance controls. These often have bugs which are only revealed by measurement, for example, a very popular soundcard gives well matched output levels on both channels but then develops a 1dB channel difference error forevermore once the balance control has been touched, even in the central position! Such hidden problems can lead to all sorts of assumptions about 'subtle loss of stereo image' in subjective tests, when in fact measurement is revealing a simple fault. In an ideal world, it should be possible to bypass all frills and work to standard input and output alignment

levels, and on a few 'professional' cards this is so. It should also be possible to click on a 'digital monitor' button to put the A-D and D-A in cascade for a simple in-out quality and level check, but surprisingly this easy-to-implement feature is almost never present. In view of these and other deficiencies, serious users are advised to treat mass-market cards that claim '24-bit 96k' performance with scepticism, until validated by measurements. More basic units with standard input and output levels and minimal controls, may give similar performance, and a better chance of working with a known entity!

Sound cards should first be tested for playback (D-A) only quality and output alignment level, by downloading a test file (SEQ3) from the Lindos website (MP3 is fine) and playing it in a media player such as 'Real-Player' (available as a free download), or 'Windows Media Player' with the MS10 in SEQ mode. The results will usually be much worse than for a CD player, though there is no fundamental reason why this should be so apart from inadequate design. Most sound cards do not conform to any standard with regard to input and output levels. Excessive noise is common, often the result of general computer 'hash', or just analog amplifier noise. Because this noise is often introduced at the final analog output stage, it will usually be found necessary to have the output level slider set to maximum for acceptable results, though there is no guarantee that this will not result in clipping at full-scale level. If it does, a second run with the level turned down should be tried.

Testing the input (A-D) performance is more difficult because of the need to establish correct input alignment level by trial and error. It is important to realise that most sound cards use a complicated analog mixing scheme such that monitoring the output directly gives no indication of digital performance or level. It is therefore necessary either to make a recording, using 'RealRecorder' for example, and play it back, or to use editing software. The aim should be to establish the input level needed to produce the same output as was measured at alignment level from the test file (the 'Test Level' figure in the result sheet), after which a sequence can be captured at this level. An added problem though, is where to set the input level sliders that appear in 'Windows'. Setting them fully up will often result in excessive input sensitivity and hence a large contribution of noise from the analog input circuits of the card and from hum loops in the input cable. Too low a setting will result in front-end overload of the card prior to its analog gain control stage. Incredibly, there is usually no 'calibrated' position, and no specification of max input level!

Most PC sound cards fail to achieve the (weighted) noise performance of Lindos 'Grade A' (-60dB) even though this falls some 6 to 8dB short of proper '16-bit' expectations. Another common failing, especially for on-board computer sound, comes not from any subtlety of distortion or frequency response, but simply from the lack of a proper 'reconstruction' filter, and presents as audible beats or roughness on high frequency tones (5 to 15kHz). Any D-A convertor needs a low-pass filter after it to 'reconstruct' the samples into the waveform they represent. The common assumption that this filter is

only needed to remove supersonic components that will not be heard anyway is mistaken. High frequencies come out of a digital system amplitude-modulated prior to reconstruction. They look like amplitude-modulated waves on an oscilloscope, and they sound either modulated or (if the modulation frequency is high enough) 'rough'. They may also have higher than expected peak amplitude, which can lead to unexpected clipping. The MS10 does not currently implement a test for this problem, so listening carefully while slowly increasing the frequency in fine steps, or viewing the waveform on an oscilloscope (or spectrum analysis) is recommended where poor filtering is suspected.

Segment h (headroom test) may be found useful when testing cards with unknown sensitivity. This produces a plot of output level versus input level in 1dB steps in just 5 seconds, and clipping will be clearly seen as a flattening off of the graph above a certain point. Because it is actually measuring the peak of the sinewave (though reading rms equivalent of course) this test produces a sharp flattening off of level that would not be apparent if the measurement was rms.

Segment I (long noise plot) may also be found useful, because audible clicks produced when drives turn on or off, or buzzes as programs run, are often a problem on PC sound. Playing a test CD on one PC was found to produce clicks every second or so, at a weighted level 30dB worse than normal noise level (Weighted Quasi-Pk measurement is designed to assess such clicks according to audibility). The long noise test produces a 20-second plot (one channel only) of noise, in addition to peak and mean (of the Wtd Quasi-Pk) figures, which gives a reasonable guarantee of freedom from clicks.

The best solution to the soundcard problem is to use a professional digital convertor with SPDIF or AES3 digital connections to the computer, but even this is fraught with problems, because some sort of 'soundcard' is needed to get digital audio in and out of the PC, and once again the most popular cards suffer a major defect. Though they do not reveal the fact, they actually work internally at 48k (or 96k) sample rate, and use crude conversion for 44.1k working. This can produce the surprising result of a frequency response with +/-1dB ripple even when the convertor being used has no perceptible ripple – again the sort of error that would be put down to other subtleties on listening tests but is instantly revealed as a crude fault by measurement! Ripples in frequency response of 1dB are not too important in terms of level change, but may be audible as coloration because of the phase shift, time smearing, and ringing they are likely to be associated with. Sample-rate conversion is always undesirable unless absolutely necessary, and any form of digital processing, even level adjustment, is likely to give rise to worsened noise performance.

9.3 Testing MP3 Players

Test files are available at www.lindos.co.uk for free download in MP3 form. Start with SEQ3, at -15dB FS which can be loaded into the MP3 player over a USB connection, or in some cases copied directly to a flash memory card. Some players appear in Windows as storage devices, others require special software to be installed. The tiny portable players have output levels around 20dB below UniSon level, and may only have a headphone socket. Start with the volume set to maximum, and only reduce it if clipping is suspected on the $+15\text{dB}$ distortion result. Normalisation should take care of the low level. Just press SEQ and play the sequence into the MS10 to obtain a full set of results in Lin4Win. Erratic FSK triggering is usually an indication of spurious supersonic output - inadequate 'reconstruction' filtering.

Players that use plug-in flash (usually SD) cards are very convenient, provided that they work from standard MP3 files (some don't), because a card with sequences on it can be kept for testing and just slotted in.

Bandwidth limitation seems common in most MP3 codecs (Coder-Decoders), and our test files, made using RealPlayer Gold, are typical, rolling off sharply above 11kHz (96kb/s) and 16kHz (128kb/s and above). The AAC (Advanced Audio Coding) option in RealPlayer extends to 20kHz. For MP3 testing we therefore recommend using the 128kb/s test file. On a good player this has a noise floor around -64dB and distortion residues around -65dB , both excellent figures. The use of higher bit-rates does not improve test results, though by common consent 128kb/s probably generates artefacts on program material that are occasionally just audible and can be reduced by using higher bit rates. All codecs are not equal, so do not judge MP3 quality at a given bit-rate without reference to the codec used; some early ones had major defects.

Where codecs are used for broadcast, for example in television sound, they may introduce hundreds of milliseconds of delay, which has to be corrected for by a matching delay in the video path. The MS10 measures path-delay (latency) on sequence tests, from 1ms to 10secs ($\pm 0.05\% \pm 1\text{ms}$) and shows it under 'Test Level'.

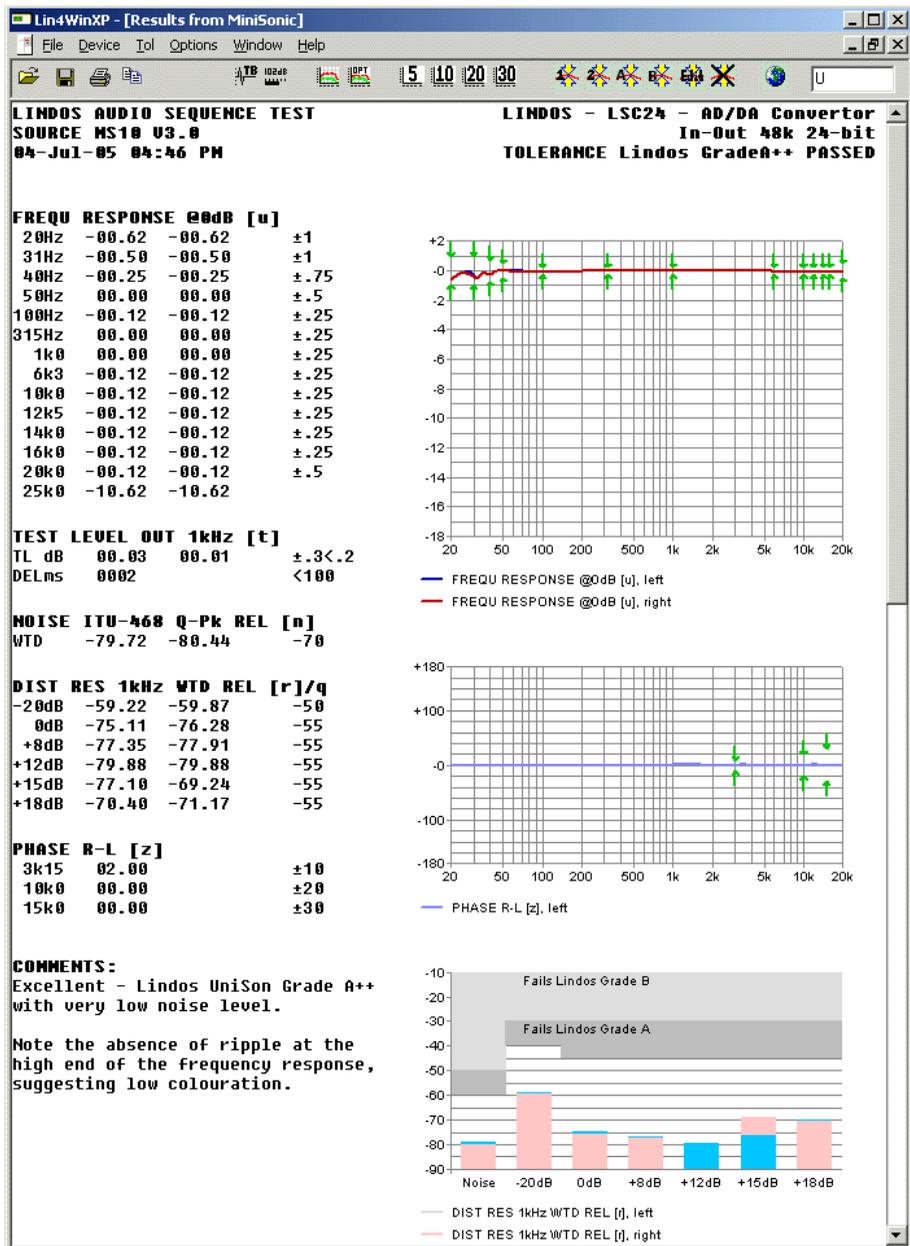

Fig 2 A Typical Results Sheet for a good 24-bit Digital Converter

9.4 Testing A/D and D/A Convertors

All of the above comments on measuring sound cards apply to Digital Convertors, except that they are usually much easier to test because they come with standard input and output alignment levels, and often with a 'digital monitor' switch. Where no such switch is present, it is easy to connect the digital (AES3 or SPDIF) output and input together in order to make a through measurement of input-to-output performance. Output-only (D-A) performance can be tested using a digital (SPDIF or AES3) signal from a PC playing downloaded Lindos test files (SEQ3 or 4). Alternatively, it may be possible to feed digitally from a CD player (SPDIF or Optical) and use Lindos Test CD (CD2) to play sequences.

While the lowest noise level obtainable from a 16-bit device is around -68dB , 24-bit devices might be expected, on purely theoretical considerations, to be 48dB better (6dB per bit). In practice, it is other factors like analog noise, sample and hold errors, and digital interference that limit the noise floor to around -80dB (468-Wtd). Nevertheless this can be regarded as excellent performance. 24 bits is a standard only because it fits the concept of 8-bit bytes, needs no dither, and is potentially 'better than we will even need'. It is only really advantageous in recording situations where peak levels cannot be anticipated accurately, because it allows recording at a low level (lots of headroom) without adding to the noise floor of the microphone preamp. Finished recordings, especially multi-tracked recording which necessarily combine the noise from many microphone preamps will almost always have a level of noise high enough to make the noise floor, even of good 16-bit digital coding, irrelevant.

High sample-rate convertors (96 or 192 ks/s) can be tested for frequency response using SEGw (40Hz to 40kHz sweep). This will reveal whether the designer has chosen to roll off the response gradually above 20kHz for minimal ringing, or rapidly at 40kHz.

Some convertors can occasionally function in a 'partially locked on' mode, having failed to synchronise properly, perhaps on a change of sample rate. Watch out for this, and other erratic failures of start-up as they can cause a significant increase in noise which, though obvious on measurements, could easily go unnoticed on programme material – a new hazard in the digital age.

10.0 Analog Equipment Testing

Most professional analog equipment can be connected using the XLR leads, and tested without any adjustment of levels, as it is probably designed to work at an alignment level of 0dBu (corresponding to the Lindos UniSon standard). There is no such thing as 'Full Scale' in an analog device though, and while mixers and processors can be expected to work happily up to +18dB or more, others, especially analog tape machine may soft limit without actually clipping at any particular level. Running SEGH (headroom) is a good way to establish if any limiting or clipping is occurring. Just hold SEQ and press LEV on the unit (or enter h into Lin4Win) and the resulting graph will clearly show the transfer characteristic in 1dB steps.

10.1 Coping with Consumer Equipment levels

A special feature of the MiniSonic is its UniSon input circuit which gives twice the gain when only side, (the +pin) of each input is connected, provided that the other (the -pin) is left open circuit. Its UniSon output circuit, being centre-grounded, also generate half the set level when connection is made to only one side and ground. Using the Phono leads supplied therefore, an oscillator setting of 0dB will result in a signal level out of -6dBu, which in turn will result in a measured reading of 0dB for a direct connection. In other words, if an alignment level of -6dBu can be assumed for the equipment under test, and Lindos supplied phono or mini-jack leads are used, then no further attenuation or level correction is necessary – just proceed as for professional equipment.

This is a neat concept, which Lindos is promoting as part of the UniSon standard, offered on the Web in the hope that design engineers will consider adopting it on all consumer equipment. As well as being conveniently half of the professional level, -6dBu (388mV rms) is a sensible choice of Alignment Level. In fact, many televisions and video recorders operate at around this level, and some specify it (though without any proper definition in terms of peak transmitted levels). A figure of -10dBV (316mV or -7.77dBu) is often assumed for consumer equipment, though this has little meaning unless defined with reference to permitted headroom. CD players are often specified as giving 2.0V (+8.23dBu) out at FS (full scale) corresponding to an alignment level of -6.77dBu with 15dB of headroom. The Lindos UniSon standard of -6dBu Alignment Level is therefore a reasonable level to use with a lot of equipment, especially if a test CD based on 15dB of Headroom is used (the Lindos CD2 test CD has all tracks duplicated with 18dB and 15dB of Headroom for this reason). Broadcast systems, such as NICAM and Digital television, and Digital Audio Broadcasts (DAB) tend to use varying amounts of headroom, and it would be a good idea if all set-top boxes, DAB tuners etc were aligned to give -6dBu out for PPM4 (0dBu) at the studio-to-transmitter feed. Miniature devices such as MP3 players, which are often powered from a

single cell, tend to give lower levels than standard, though it would not be impossible to make them conform to UniSon.

The simple way to test consumer equipment is to assume an alignment level of -6dBu (the UniSon standard) and see how much headroom results. Where input and output level controls are provided on the equipment, it is a good idea to adjust these for optimum performance at Unison level in and out, and mark them for future reference. Other alignment levels can of course be used, but remember that 0dB on the MiniSonic represents -6dBu both in and out on the MiniSonic when single ended connections (such as phono or 3.5mm minijack leads) are used. See the UniSon pages at <http://www.lindos.co.uk/unison.html> for further details of this concept.

10.2 Testing Analog Tape Machines

The process of recording and replaying an analog tape involves many stages of 'equalisation' to compensate for the many factors that cause deviation from a flat frequency response. The recording amplifier will usually include a lot of high-frequency boost, mostly to compensate for 'partial bias erasure' at high frequencies while the replay amplifier will essentially have a falling 6dB/octave response to compensate for the fact that the voltage induced in the replay head rises with frequency, being dependant on the rate of change of flux. This makes standardisation between machines, very difficult, and in practice standardisation is achieved by adjusting the replay equalisation for a flat response from a carefully made Test Tape. Fortunately, the replay performance of a tape machine is much more stable than the recording side, but ideally this should still be checked using a commercial test tape.

The first adjustment to make is of head azimuth, using a test tape that can be assumed to have been recorded with a gap that was perfectly at right angles to the edge of the tape. Mechanical adjustment of the head tilt, for zero phase difference between channels, is made while playing a 10kHz to 16kHz tone. Although phase difference causes shift of stereo image this is not the main reason for the adjustment, because the ear only uses phase difference as a directional cue below about 2kHz, where phase error due to azimuth error will be insignificant. It is the loss of high frequency response caused by azimuth error that is important, and even worse, the loss that results when both channels are combined to give a mono signal (broadcast signals need to be reproducible in mono without such loss). Phase difference is simply the most sensitive measure of azimuth alignment.

The replay response can then be checked by playing a succession of tones from a test tape and noting the level at each frequency. The Tape speed can also be checked by measuring a standard frequency track using the MS10 with Lin4Win, or by using the speed check option on a 3.150kHz recording. Where a trusted reference machine is available, this may be used to record a sequence (SEQ6) to produce a test tape for routine checking, but reference to

a lab-standard tape is ultimately desirable.

Once the replay characteristics have been established, record-replay tests and adjustments can proceed. Most professional (2-head) machines can record and replay simultaneously, which makes adjustment easy. Sequence testing is ideal in this situation, because FSK triggering ensures that the time delay between record and replay has no effect on the results.

Frequency Response is best tested at -10dB AL (10dB below alignment level) on tape machines, since their high frequency performance degrades above this level. Testing at -20dB used to be recommended, but while this may give better results it fails to show up severe restriction of high frequencies that can occur even at typical levels on some machines. Attempts to equalise analog tape machines at 0dB AL will usually result in over correction at low levels, making for too bright a sound.

SEQ6 is ideal for testing tape machines as it uses SEGV (sweep at -10dB) and also the master-seg SEGm which modifies the noise and distortion segments to use a higher range than normal. This enables it to cope with the relatively high levels of distortion and that are to be expected from tape. SEGm also incorporates a period of 3.15kHz tone on which tape speed is measured, which is only valid if the recording was made at correct speed of course, and it uses 400Hz rather than 1kHz for the 'test level' check – preferred because it falls below the region affected by any equalisation errors. Analog tape machines will usually have only 12 to 15dB of headroom, conventionally defined in terms of 3% third harmonic distortion. Using the MiniSonic, the predominantly third order distortion component (at 3kHz) is emphasised by 8dB in the weighting filter, and high-frequency noise modulation may add to this, so a figure of -20dB (10%) for Distortion Residue is not unusual at high levels. This shows just how bad analog tape is compared to digital systems, when measured in the most meaningful way.

While the additional running of SEGq may provide useful information about distortion at higher levels on some machines, SEGh is recommended for a most revealing test of the overload characteristic up to +18dB. This segment plots output level versus input level in 1dB steps, and will usually reveal a gentle soft-limiting transfer characteristic with no definite clipping point. It was this soft-limiting of course which made analog tape so forgiving of brief overloads when compared with the harsh clipping of digital systems.

10.3 Testing Compact Cassette Decks

Compact cassette machines are tested in the same way as open reel tape machines (see above), but because of the low tape speed and narrow head gap, results are much less stable and more sensitive to head contamination, tape type, head alignment and bias setting.

Azimuth head alignment, the first thing to check, will be found to be particularly problematic. The low tape speed (4.75 cm/s) of compact cassette results in a wavelength on tape at 10kHz of about 5 microns (0.00475mm) so that an error in alignment of just one micron between heads will cause 90deg of phase error. One micron is very small indeed (1/25th of a hair-breadth), and maintaining this degree of alignment between machines is almost impossible, with some surprising results. A test cassette recorded on both 'sides', for example, may show zero phase error on the machine that recorded it, yet show significant phase error on one 'side' only, when played on another machine. How can this be? The answer is that tape stretch takes place as the tape crosses the head, and if the pressure applied to the tape across the head surface is not even, then the tape will skew. This is of no consequence so long as the skew is always the same, but different machines will have different head friction characteristics and this will lead to different amounts of skew! Coupled with this is another effect. The tape has to wrap round the head surface, which is curved, to ensure contact at the gap. The distance travelled over the head depends therefore on the length over which contact with the head is maintained by the pressure pad, and if the pressure pad is not perfectly square and uniform, skew will again result. There have been attempts to market 'reference shell' cassettes, but they never succeeded in eliminating these effects, and the real weakness of cassette was always its low tape speed.

We have discovered frequency response anomalies in testing cassettes, which also appear at first sight to defy reason, and though they may be of academic interest now, they are interesting in retrospect. Two test tapes, each made on a Denon 2-head machine, with bias adjusted in each case to optimise performance, were found to play back differently on another (single head) machine (-5dB at 10kHz), though they played flat on the Denon. A tape made on the second machine played back perfectly well on the Denon, and in all cases azimuth misalignment was not the cause. How can such 'reciprocity failure' exist? The answer seems to lie in the fact that a two head machine

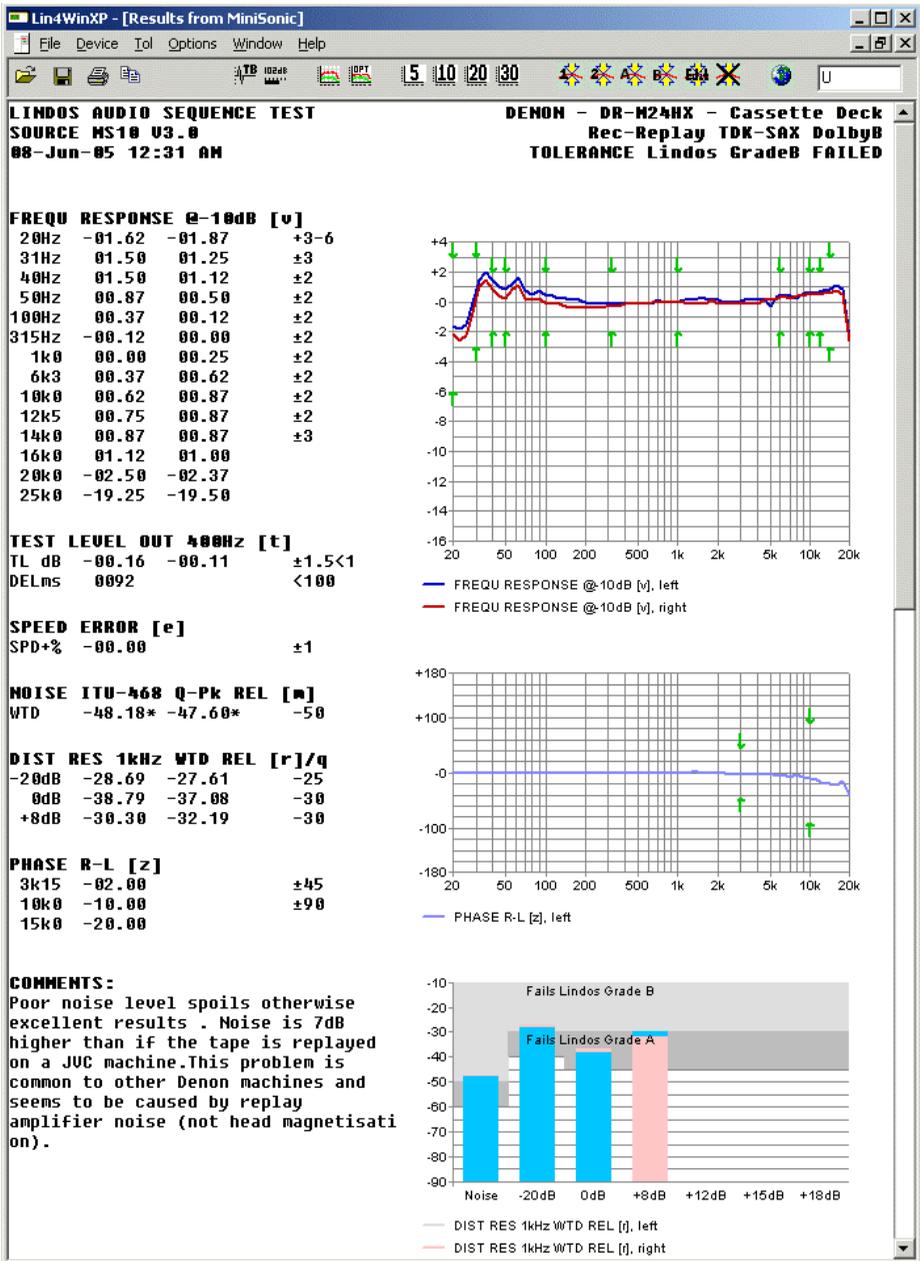

Fig 3 A Typical Results Sheet from a Compact Cassette Machine

usually uses a wide-gap recording head in order to magnetise the tape more deeply than is possible in a single-head machine, the aim being to get more signal off the tape and reduce relative noise. The deeper magnetisation can be laid down at a different position – out of phase at high frequencies with the surface magnetisation, by an amount dependent on bias level. This is of no consequence when played back with the very narrow gap of a two head machine, which responds mostly to surface magnetisation at short wavelengths, but can result in cancellation between the layers when sensed by the wider replay gap of the single head machine – hence the high frequency loss. The TDK SAX tape appears to eliminate this problem because it uses two layers of different oxide, each optimised for a different bias level. Magnetisation is laid down at the ‘exit zone’ where the high-frequency bias amplitude falls to a critical value that no longer erases the tape, and in normal tape this exit zone shifts with depth. So there never was compatibility between cassette machines, no matter how well they were set up, and how pre-recorded tapes really performed is anybody’s guess!

A test cassette is available from Lindos, for checking replay response. It is recorded with SEQ6, preceded by 8-second tones at 3.15kHz, 10kHz and 1kHz, to permit azimuth alignment and speed adjustment. If sequences are recorded for use as test tapes it may be useful to use SEGt instead of SEGm as the master-seg. This adds in the 8-second tones. Note that special segment characters < and / can be used in Lin4Win to generate complex test tapes. For example:

tvrz<4 repeats a tape test sequence ten times (with 8-sec tones)
tvrz< repeats indefinitely
t/mvrz/mvrz/mvrz<10 sends tones, then 3 sequences, ten times

The special characters require that a path exists to enable the MS10 to respond to its generated sequence, because Lin4Win waits until the downloading of results is complete before continuing after the / or < symbol.

Record-replay performance is easily checked by running SEQ6, and on two-head machines bias and record equalisation can be adjusted, either by using fixed tones, for example to optimise the response at 10kHz, or between sequence runs. On single head machines, it is necessary to record the sequence, wind back, and replay, before making adjustments and trying again; a process that was extremely tedious before sequence testing.

Typical results for a good compact cassette deck (chrome tape and Dolby B) are –55dB Noise (468-Wtd) and –37dB Dist Residue at 0dB, though many machines will fall short of these figures. Although it was primarily designed to reduce noise, Dolby-B also reduces the audibility of modulation noise and distortion products significantly. This can be particularly apparent on the Distortion Residue measurement at –20dB.

10.4 Testing Power Amplifiers

The standard way to test Power Amplifiers is into a dummy load (8 or 4 ohms) but this needs to have quite a large heat sink capable of dissipating the necessary power. It is also not representative of the actual load presented by a loudspeaker, which contains reactive components (inductance and capacitance), so the only truly valid way to test any amplifier is with the loudspeaker that it is to be used with. If this is attempted, great care should be taken to avoid overheating the drivers, especially tweeters; limit periods of high level to a few seconds. Low to medium power amplifiers can be tested at levels up to around 0.5 watt by connecting the MS10 input directly across the speaker output, and this is best done using both pins (differential input) because even though the speaker output and amplifier input usually share a common ground connection, the high output current involved is likely to cause ground voltage differences between input and output, which may lead to feedback and oscillation at high frequencies if a power amp's input and output ground pins are connected together. Use the XLR leads with an improvised connection into the + and - input pins (no ground connection necessary on the input - this is provided by the oscillator output), or use a special lead. A good starting point is to set the oscillator level and volume setting to produce 0dBu into the MS10 (0.775V rms or 0.075 watts into 8 ohms). Run SEQ2 to obtain a complete set of test results including distortion up to +8dB (0.473 watts into 8 ohms). Higher levels than this necessitate the use of a special resistive attenuator on the input, as otherwise the +12dBu input capability (unbalanced) of the MS10 is exceeded. Appendix D gives details of a typical one - consult Lindos if in doubt.

Power amplifiers have traditionally been accused of sounding different because of crossover distortion, and huge efforts have been put into reducing measured THD (rms total harmonic distortion) to ridiculously low levels. This is an unscientific approach, because there is no level of THD that can ever be said to be good enough. The many theories of how high-order distortion should be assessed all seem flawed, because they attempt to deal with the mathematically equivalent steady-state power spectrum without recognising that our ears do short-term frequency discrimination. We hear crossover distortion as a series of 'clicks' and a good tool for assessing the audibility of clicks already exists in the 468-Wtd Quasi-Pk noise measurement standard. Because it uses 468-weighting on distortion measurement, the MS10 does a good job of assessing the actual audibility of crossover distortion. An amplifier with 0.1% (-60dB) of purely 3rd harmonic distortion will read 0.3% (-51dB) on the MS10 because the weighting curve is 9dB up at 3kHz. Another amplifier may measure 0.05% (-66dB) THD yet also read 0.3% (-51dB) on the MS10, reflecting a harsher form of crossover. Distortion residue below -50dB (0.3%) is probably inaudible, and below -60dB (0.1%) quite irrelevant.

10.5 Testing Loudspeakers

Speakers can be tested using one of the Lindos miniature microphones plugged into one of the MiniSonic mic inputs. These inputs conform to the UniSon-mic standard, with 5V power on the tip of the minijack and a sensitivity of -30dBu (for 0dB on the scale).

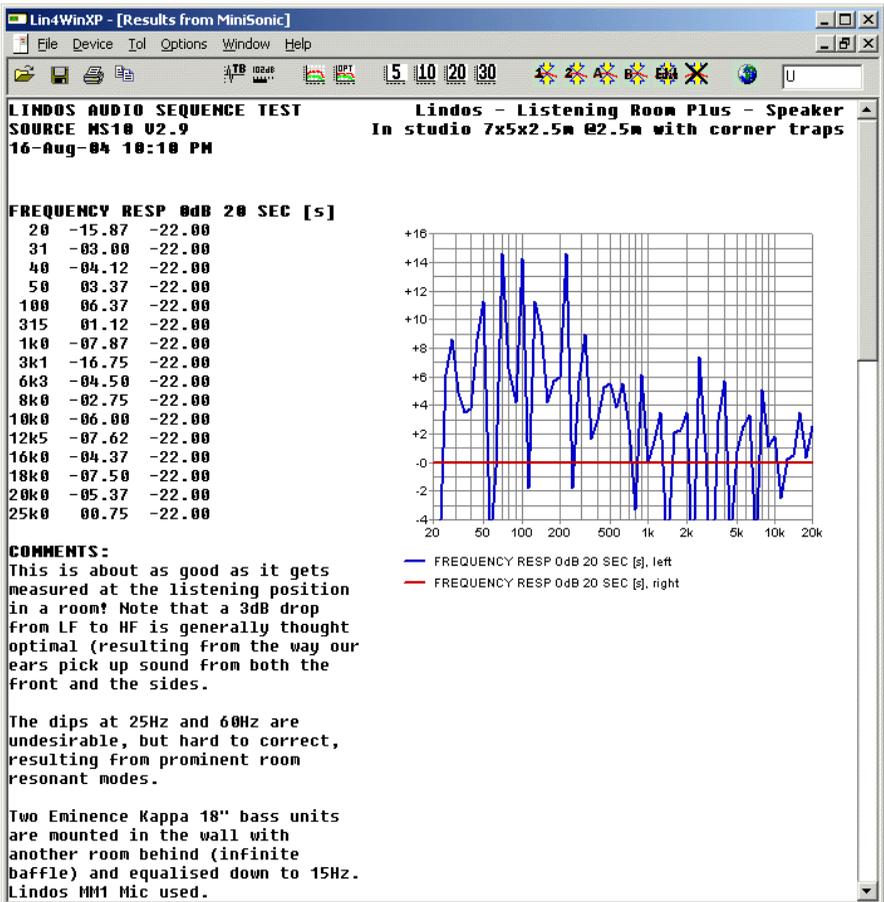

Fig 4 Results Sheet for a Monitor Speaker @2.5m in a Room

Lindos microphones, are carefully calibrated by us (with a pair of selected resistors in the gold-plated mini-jack) to produce a standard output of -30dBu at $100\text{dB SPL} \pm 0.5\text{dB}$ (UniSon Mic Standard). They can be used for loudspeaker testing, acoustic noise measurements, and in matched stereo pairs for live recording. The MM3 is extremely flat from 20Hz to 20kHz (typically $\pm 1\text{dB}$). The MM2 offers lower distortion at high levels, but with some 20Hz loss. When using microphone inputs, ensure that the MIC toggle switch is set to MIC and that nothing is plugged in to the normal D-type input

sockets. Where protective caps or windshields are supplied, these should preferably be left off for measurements, as they can introduce 20kHz loss..

The standard way to test a loudspeaker requires a fully anechoic chamber, with an acoustically transparent floor-grid. The microphone is normally mounted on an unobtrusive boom and positioned 1 metre in front of the drive units on axis with the high-frequency driver. While this will produce repeatable results, we would argue that more relevant measurements are very easily made outdoors using the 'half-space' method described below.

Measurements made out of doors will usually show ripples in the mid-range caused by ground reflections interfering. Raising both speaker and microphone on poles has been used as a way of reducing ground effect, but there is a much easier way: simply lay the speaker on its back pointing at the sky. Ground reflection will still interfere, but will be greatly reduced in the mid-range because most speakers are directional, and only radiate very low frequencies backwards. Putting a folded quilt under the speaker will reduce mid-range ripple by absorbing rear radiation. At low frequencies, the ground reflection is always in-phase, so that the measured response will have increased bass, but this is what generally happens in a room anyway, where the rear wall and the floor both provide a similar effect. There is a good case therefore for referring to the method as 'half-space' measurement, and aiming for a flat 'half-space' response. Speakers that are equalised to give a flat 'free-space' response, will always sound very bass-heavy indoors, which is why they tend to incorporate 'half-space', and 'quarter-space' (for corner use) options bringing in attenuation below about 400Hz. It makes more sense, arguably, to design for half-space use in the first place, and only boost the bass for open-air use! This method has been used to measure known, very flat, speakers, with excellent results. Digging a hole and burying the speaker flush with the ground should work even better, creating the loudspeaker equivalent of the 'boundary effect' microphone (all reflections precisely in-phase) but any rear port, must of course be kept open.

Measurements on a single speaker in a listening room, though less satisfactory, can be interesting. At low frequencies, most rooms have resonances at a series of frequencies where a room dimension corresponds to a multiple number of half wavelengths. Sound travels at roughly 1 foot per millisecond (1100ft/s), so a room 20 feet long will have resonances from 25Hz upwards. These 'resonant modes' cause large peaks and dips in response. A speaker in a room does not really 'radiate' low frequencies at all, but couples into the 'room modes' – resonant standing wave patterns. Because this coupling is impedance dependant, it cannot even be predicted from measurements made of speaker radiation alone. Put simply, some speakers present a very 'stiff' driving force and will drive a resonant pressure peak at a boundary more efficiently than a 'floppy' one. Dipole loudspeakers, such as electrostatics or ribbons, couple to the room differently, by velocity rather than pressure, and are generally thought to excite resonant peaks less.

All multi-driver speakers are prone to 'suck out' in the crossover region between units (often around 3kHz) if the microphone is placed slightly above or below the optimum axis, because the different path length from two drivers producing the same frequency leads to phase cancellation. It is useful to remember that, as a rule of thumb, 1kHz has a wavelength of 1 ft in air, and 10kHz a wavelength of only 1 inch. Published results are often only valid for very precise positioning of the microphone to within a centimetre or two.

Measurements made at 0.5 to 1m are useful when it comes to speaker optimisation, because at this proximity the radiated sound predominates over reflections from walls, at least at high frequencies. Measurements made at 2 or 3m, in the actual listening position between two speakers can be much more revealing of what is actually going on in a listening room. Horrendous though the resulting frequency response may be, it provides a basis for real experimentation with absorbent panels or resonators. Driving both speakers is recommended, as this is the only way to stimulate low-frequency room 'modes' in a representative fashion – driving at one corner would be very bad. This does mean though that the microphone must be positioned precisely equidistant from the two speakers if a 'comb-filter' effect of alternate peaks and dips is to be avoided. Positioning is best done by moving the mic from side to side for maximum response on a 1kHz tone, then a 3kHz tone, then a 10kHz tone. Beware of applying carpeting or other thin absorbent materials to large areas of wall in a listening room as this will result in an unnaturally 'dead' room at high frequencies while having no effect on reverberation at low frequencies. Glass-fibre or foam 100mm to 500mm thick is necessary to damp down low frequency modes. An alternative approach to low-frequency absorption is to space hardboard panels several inches away from the wall, backed with glass fibre to damp their vibration.

Measurements at less than 1m will not allow proper combining of the radiation from separate drivers around the crossover frequency. Even if the path lengths are the same the tweeter will be 'off-axis'. Very close measurements can be useful though. Placing a microphone carefully on axis a few centimetres in front of a tweeter will allow the high-end response to be measured with minimal room effect. Similarly, placing one a few centimetres in front of the voice coil of a bass driver will give some indication of how it is responding (but not of the output from ports if these are present).

To minimise interference from ambient noise, the oscillator level and amplifier volume can be set to give a reading of 0dB (100dB SPL), but this is quite a high level, and should only be applied briefly (using the MUTE button to turn the oscillator on and off) unless the system is known to be capable of continuous drive at these levels. A level of 90dB SPL will be more appropriate for smaller speakers. Ear defenders should be worn, as exposure to continuous tones at high level can lead to hearing damage and long-term tinnitus! Running SEQ1, a 5-second sweep will provide a reasonable starting point, but SEQ5 (20-second sweep) is to be preferred as it allows time for

resonant modes to build up and decay, giving a response curve with finer resolution and a more representative (if worse looking!) result. For greater resolution when using levels below 100dB SLP press and hold normalise first on a 1kHz tone, before running a sweep (or set manual gain using PPM).

Automatic triggering of sequences from FSK via the microphone works reliably in most situations, but in very reverberant rooms, or when measuring sub-woofers, or bass drivers at very close range (with severe attenuation of the FSK), use 'direct trigger' (startup option 4). Two microphones, each very close to a driver, can provide a powerful check of whether crossover filters are really producing the phase shifts intended around the crossover region.

While the very best modern speakers can produce a frequency response flat to +/- 1dB from 40Hz to 20kHz in anechoic conditions, measurements at 2m in a real listening room can be considered good if they are within +/-12dB, and efforts to produce anything like a flat response below 100Hz are likely to provide endless scope for experimentation! This is where the real challenge of audio quality lies, and having succeeded in building a listening room and speaker set-up that is reasonably flat down to 20Hz we can testify to the fact that a response flat to 30Hz content really makes a difference, while 20Hz may possibly make a difference, mostly on bass-drums.

Using an equaliser to correct for room response is a poor solution, especially at low frequencies, because it relies on reducing the drive at resonant modes to produce a flat 'steady state response' once the resonant mode has built up and stabilised, and this can take many tenths of a second. The result is 'sluggish' bass, because the initial wave-front has been greatly reduced by the equaliser. Bass drums, and bass guitar, produce low frequencies with sudden onset, and the initial wavefront accounts for much of the impact that is both heard and felt. Realistic reproduction requires both the initial radiation and the steady state level to have a flat response, and there is no easy way to achieve this - room modes just have to be eliminated. The commonly recommended approach of moving speakers around in an attempt to stimulate the maximum number of modes is also not valid. It amounts to the same thing as using an equaliser - adjusting the coupling of the speaker to the mode as a way of controlling the steady state level, but at the expense of the initial wave-front, with sluggish results. It should be clear from all this that the concept of a 'fast' bass driver is utter nonsense. It is often claimed that small bass drivers are 'faster', being able to accelerate more quickly. Yes, a light cone is easier to accelerate, but this is only the same as saying that a light cone can reproduce higher frequencies. Given that a driver can generate a given frequency, its ability to generate higher frequencies; its bandwidth, has little to do with the rate at which a low frequency tone builds up or decays. Provided that the driver is operating at reasonably low 'Q' (a feature of the driver plus its enclosure) then its contribution to the sluggishness of bass response is likely to be negligible. This is less true of reflex designs, though they remain popular simply because it is rare to find a room in which their defects are not swamped

by resonant modes.

Distortion measurements on speakers can only go as low as the distortion of the measuring microphone itself of course, and for best results at high levels (100 to 120 dB SPL) the MM2 is to be preferred. Although the MiniSonic only normally measures distortion at 1kHz it incorporates a high-pass filter that attenuates all frequencies below 2kHz (second harmonic) (-42dB @ 200 – 59dB @ 100 –70dB @ 40Hz). This make possible a useful ‘Rub and Buzz’ test, over the 20 to 200Hz range. Just press DIST and then vary the oscillator frequency around the bottom end. The resulting quasi-pk weighted measurement will ignore low harmonics, but give a good indication of the high frequency residue that normally results from rattles, voice coil rub, and hissing ports. Very few speakers can generate a pure 20Hz tone that is not heard predominantly as hisses and buzzes, and this test has been used on the production line of a major loudspeaker manufacturer.

It is interesting to measure actual listening levels on both live and reproduced music in PPM mode (preferably super-fast PPM), because this captures and holds the peak SPL (sound pressure level) demonstrating just how high peak levels need to be for realistic reproduction without compression. A-Weighted readings, taken on a conventional sound level meter, may be much lower, partly because A-weighting attenuates low frequencies, and partly because rms levels imply a slow averaging process. A listening level of 100dB SPL, measured A-wtd rms, might normally be considered very loud, but 100dB SPL on a PPM, though loud, is not excessively so, and still some 20 to 30dB lower than the level needed to achieve truly realistic comparison with a live band. This is interesting because most speakers have a sensitivity of around 86dB SPL for 1watt @1m, and so a level of 100dB SPL requires a power input of 25 watts (10dB represents a 3 times increase in level, but a 10 times power increase because of the square law relationship). A typical top-end speaker, driven by a typical 100watt amplifier, cannot therefore produce peak levels much above 105dB SPL at 1m (which translates roughly to 105dB at listening position from a pair of speakers in a typical listening room). Achieving truly realistic levels from such speakers would require peak power inputs of at least 20dB more (100 time power) or 10,000 watts! The use of bi-amped or tri-amped loudspeakers, where each frequency range has its own amplifier, helps solve this peak-handling problem in a way not often recognised, because peaks are usually the result of transient high-frequency bursts from cymbals, riding on sustained bass guitar notes. Interestingly, two 100-watt amplifiers have the same peak handling ability as a single 400-watt amplifier under such circumstances.

10.6 Testing Headphones

Headphones can be tested on the listener using a tiny mic tucked inside close to the ear canal entrance. The Lindos MM4 (capsule only version of MM3) is particularly suitable owing to its very small size. Set the volume for a level of 0dB on the scale (100dB SPL)(or 90 and normalise) at 1kHz and then run SEQ1. Most headphones feature a notch in the response around 6-10kHz, which is often introduced by a reflecting plate (with holes) mounted in front of each diaphragm. High frequency sounds originating in front of us reach each ear canal greatly altered by head masking and pinna (outer ear) reflections, an effect measured by so-called 'head related transfer functions', or HRTF's. The notch is a crude attempt at the very complex processing needed for proper headphone listening, which should ideally be specific to each listener's HRTF's. It reduces harshness when listening to stereo recordings, though really there is no direct compatibility between stereo and headphones. Bass is simply a function of pressure in the space between headphone and eardrum, which is too small to add low frequency resonances. Despite wild claims, like 'frequency range 4Hz to 20kHz', very few headphones actually achieve even 40Hz to 1kHz +/-3dB and many only seal effectively when held firmly against the head, which is not satisfactory. Good ones give the same bass response with or without extra pressure.

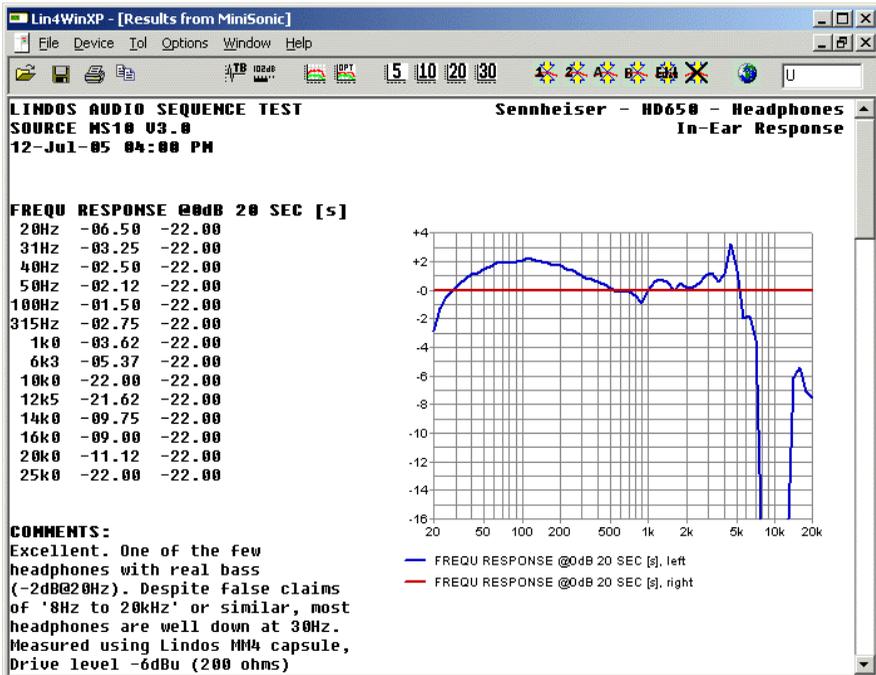

Fig 5 In-Ear Response Plot for top quality Headphones

10.7 Testing Microphones

Testing Microphones is difficult challenge, especially where directional mics, and large-diaphragm mics are concerned, but we have been pleasantly surprised by the consistent results obtainable from various miniature omni-directional mics.

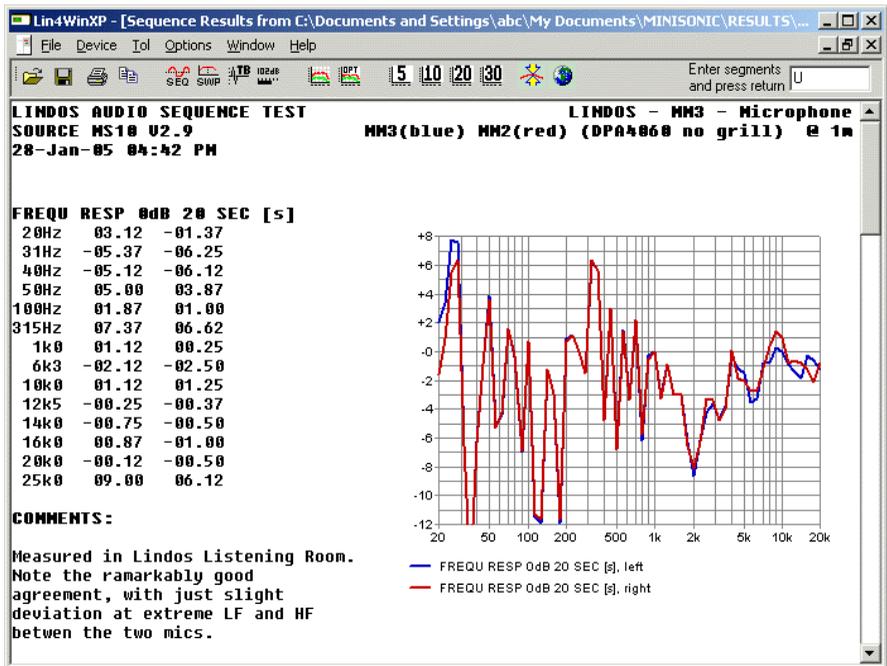

Fig 6 Simultaneous Test of two Microphones

Omni-directional mics are easily calibrated for absolute sensitivity at 1kHz using a small pressure calibrator, which typically produces a level of 114dB SPL (Sound Pressure Level), but frequency response cannot be measured in a sealed chamber because of severe chamber resonances at high frequencies. The best way to measure the frequency response of a mic is to strap a Lindos miniature measuring mic alongside it, on a boom, 1m in front of a good loudspeaker, run a stereo sweep, and compare the two channels of the response plot. This can be done using the two microphone inputs on the MS10, or even by using one mic input for the measuring mic, and one normal input fed from an external mic preamp (using only the -ve input pin which remains active when MIC is selected.) Avoid having any object bigger than 10mm or so in the vicinity of the microphones –even the presence of a larger mic will affect the soundfield in the vicinity of the test mic. Small mics, however, can give very well matched results right up to 20kHz.

SPL is defined relative to 20 μ Pa (micro Pascals) and microphone outputs are usually quoted in mV/Pa. 1Pa is equivalent to 94dB SPL. 1mBar is 100Pa.

10.8 Testing Microphone Inputs

Microphone inputs are often designed to accept a wide range of input levels in order to cope with all kinds of microphones. Connecting them directly to the MiniSonic and running a sequence with the input control set to max level is fine for demonstrating high level performance and clipping levels, but it is never advisable to test mic or other high sensitivity inputs at low levels using a simple connection because the output noise of the MS10 together with any hum and noise picked up by the input cable is likely to be above the noise floor of a good preamp. Instead, use a special lead with a simple resistive attenuator (-20 to -40dB) built in, so that only thermal resistor noise predominates at the input. This will allow the true noise performance to be measured, along with low-level distortion. With a suitable choice of resistors, the source resistance can also be chosen to be representative of real microphones (200 ohms is often considered a standard). See Appendix D for details of a suitable attenuator lead.

11.0 Broadcast Testing

Sequence testing is widely used for testing entire broadcast networks, from studio to transmitter, and a useful feature of Lindos units is their ability to ignore music and speech and only trigger on appropriate FSK signals. An MS10 left connected to a radio receiver for hours on end will ignore programme material, but capture and store results from any sequence test that is transmitted. If it is connected to a PC running Lin4Win, multiple tests will each leave a page of results on the screen for later analysis, saving, printing or uploading to the Lindos Test Sheet Database for public viewing.

Although the use of 600ohm inputs and outputs can no longer be considered standard practice in studio environments, it is still sometimes used on long cable runs, and on telephone lines adapted for use as 'music circuits'. It is also common to use a source impedance of 75ohms when testing such circuits, this having been found to result in a better high frequency response with no ill effects, since reflections are suppressed by the (matched) 600ohm termination. Special leads can easily be made up containing two resistors (33ohms or 295ohms) to raise the output impedance of the MiniSonic, but remember to raise the output level of the oscillator to compensate for loss (by 1db for 75ohms or 6dB for 600ohms).

Path latency (time delay) can be important on long cables and satellite links, and the MS10 displays this in milliseconds when a sequence is run (see section 5.9). This only works of course when a complete return path is available so that the same MS10 is sending and receiving.

11.1 Special Level Considerations and Pre-emphasis

Special rules may apply in broadcast environments that protect the final transmitter, and also distribution lines, from overload. The EBU (European Broadcasting Union) has set a maximum permitted level of +9dB AL for this purpose, as well as stipulating that test tones above 0dB AL shall not persist for longer than a few seconds, to avoid intrusive crosstalk between multiplexed distribution circuits. Just use SEQ2, the 'Broadcast Sequence,' which leaves out SEGq, to avoid testing at levels above +8dB AL.

When testing FM transmitters, further restrictions apply, because 50us pre-emphasis is usually applied (75us in the US), prior to the transmitter, which incorporates high frequency limiters to protect against over-deviation. This boosts high frequencies (receivers have corresponding de-emphasis), so a sweep at 0dB should not be run as it may cause overload at 15kHz. SEQ6 (Tape and FM) has been designed for safe use over transmitters, running a sweep at -10dB and also normalising at 400Hz, preferred over 1kHz as it avoids the pre-emphasis region for a more consistent result regardless of any errors in the pre-emphasis. SEGc (Crosstalk) is also safe for transmitter use, as it uses different levels at each of three frequencies, conveniently avoiding high-frequency overload as well as achieving a result that is weighted as recommended by the IBA (UK Independent Broadcast Authority – now disbanded).

It is common for broadcast feeds to incorporate alarms that warn of a complete absence of signal for an unreasonable length of time. Most segments are designed to leave the oscillator muted, to avoid the annoyance of a 1kHz tone, especially when testing speakers, but this can result in alarms triggering. SEGz, which is the last segment to run in most sequences, now leaves the oscillator generating 400Hz @ -10dB, keeping the channel occupied without being audibly annoying.

11.2 Recording Through the MiniSonic

The MiniSonic has been designed to solve a number of problems that arise in studio and location recording. Because it incorporates two low noise microphone inputs, optimised for use with high-quality electret microphones, it can be used to interface these into professional or consumer audio systems. Miniature omnidirectional electret microphones are often thought of as 'cheap and nasty' but some can in fact perform to the very highest standards. In particular, they can provide a truly flat low frequency response down to 20Hz, by virtue of being pressure-sensitive, which is not possible in even the most expensive directional microphones. Their small size, and the absence of internal resonant chambers, also makes for very low colouration at high frequencies, something not possible with directional mics.

One miniature microphone in particular, the Danish Pro-Audio (formerly B&K) DPA4060 is widely used in stage productions because of its low noise, low distortion at very high sound levels, and superb frequency response, yet it is usually used only as a radio mic with a belt-mounted transmitter, compromising quality. Where radio use is not essential the MiniSonic provides a useful alternative means of interfacing, and a pair of these microphones (sold modified and calibrated by us as the Lindos MM3), can also give excellent results on music using the 'spaced-omni' approach rather than the more usual 'coincident pair cardioid' technique. Two such mics, with lapel clips, can also provide a dual feed for interviews to a camcorder etc on location, eliminating the mechanical noise that camera mounted mics so often suffer from. Where a slightly higher noise floor is unimportant the Lindos MM1 or MM2 microphones provide almost identical results at much lower cost. A single miniature mic with a 'pop-screen' (highly recommended) can provide first-class 'voice-overs' via the MiniSonic into tape machines or digital editing systems. Being calibrated to a common standard, all three microphones can be conveniently interchanged without any alteration in gain settings.

These microphones can also be used with a miniature remote stereo mic preamp (consult Lindos for details), which is powered from the normal MiniSonic UniSon input, and returns a balanced signal allowing cables up to 100m long to be used without hum or signal deterioration. All Lindos microphones are calibrated by us (to within +/- 0.5dB using resistors fitted in the jack plug) to read 0dB on a MiniSonic at 100dB SPL. This ensures automatic balance in stereo applications, as well as providing informative level information.

The fact that the Unison output interfaces directly to Professional or Consumer equipment is valuable in such applications, and proper Peak Programme Metering is of course a bonus. The MiniSonic will also be found useful for interfacing consumer equipment to professional equipment and vice-versa, with level adjustment available. To use the MiniSonic as a recording aid, press PPM and select MIC. Holding down PPM while using the < > keys will then allow the sensitivity to be adjusted in 1dB steps over a wide range, as indicated by the 'shadowbar' and, of course, the settings are precise and repeatable. Do not forget to switch on in 'Power Lock' mode (or use mains power) for live recording!

11.3 Testing PPMs and other Program Level Meters

The Peak Programme Meter (PPM) was originally developed by the BBC as a tool for measuring programme levels consistently in recording and broadcasting. It responds essentially to the peaks of the signal, with a fairly long fall-back time that makes it easy on the eye, but with a carefully devised 'integration time' designed to make it deliberately under-read on short-lived bursts of signal. The original intention was to take full advantage of the soft-limiting characteristics of analog tape recorders by allowing brief peaks that

were of such duration and level that the resulting distortion would not be noticeable to the ear. Still ubiquitous in the UK and former British colonies such as Australia and South Africa, as well as in Europe, the PPM is much preferred to the VU meter, which was the original US solution, because the latter is bouncy, and not nearly so well standardised.

IEC268-10 lays down precise standards for the dynamic behaviour of Peak Programme Meters together with special test methods for ensuring compliance. These involve noting the peak deflection on 5kHz or 10kHz tone-bursts lasting from 0.5ms to 100ms, as well as the fall-back time; the deflection on the shortest burst being much smaller (by 17dB) than that on the longest. Further tests are needed to ensure that the meter does not overload, and therefore read low, on short high-amplitude bursts.

SEGP in the MiniSonic has been designed to test for toneburst response, fall-back time, and freedom from overload, simultaneously, without the need to refer to tables of target levels. It does this by generating five tone-bursts at decreasing (inverse weighted) levels, such that a properly functioning PPM will peak to 0dB on each of them. While this is not quite in accordance with the methods laid down in the standard, it is very quick and effective in validating PPMs in the studio environment, the elevated levels of the short bursts providing a very adequate test of overload at the same time as checking dynamics. The segment begins with 1kHz tone at 0dB, followed by a delay and then the shortest burst. Each subsequent burst is preceded by a delay, to permit decay to a value sufficient to have no effect on the subsequent peak, and this delay has been timed to test the fall-back time - the reading should decay to -20dB between bursts. It is of course possible to run this sequence at different levels in order to separate out any overload limiting, or to provide a more demanding test of overload on peaks, targeting for example +8dB rather than 0dB.

SEGP Tone-bursts are 0.5ms (10kHz), 1, 1.5, 5, 10, 100ms (5kHz) @ +17.0, +9.0, +4.0, +2.0, 0.0dB respectively, with 2.32s delays in between. All should hit 0dB with a fall-back to -20dB in between.

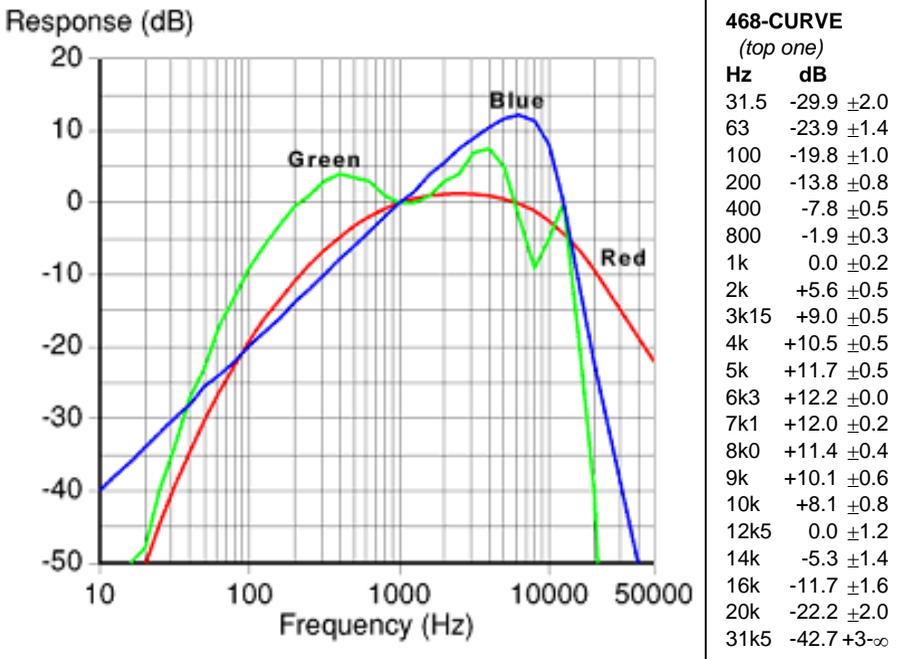

SEGb is a general purpose toneburst test segment, generating five bursts all at 0dB, useful for testing all types of programme level meter. Individual bursts (1ms to 255ms) can also be selected using Lin4Win.

SEGb Tone-bursts are (5kHz), 100, 10, 5, 1, (10kHz) 0.5ms @ 0dB with 2.32s delays in between.

12.0 Appendix A: '468-Weighting'

Noise measurements have no meaning without a bandwidth or weighting specification, because noise can contain frequencies beyond the range of human hearing. A simple rms measurement will therefore give a result that depends on the bandwidth of the instrument. While noise measurements are often specified as '22Hz to 22kHz Bandwidth' or 'A-Weighted,' neither of these methods is satisfactory, and broadcasters have long standardised on the 468-Weighting curve, originally referred to as CCIR Recommendation 468-4, but now embodied in ITU and IEC standards since the CCIR was disbanded. (CCIR468-1,2,3,4 have small tolerance differences).

CCIR-468 has its roots in a BBC Research Dept Report, EL-17, entitled 'The Assessment of Noise in Audio Frequency Circuits.' This compared several existing weighting networks (including A-Weighting) and rectifier types, in subjective experiments in which readings were compared with estimated loudness on many different types of noise, some continuous like tape noise, and others impulsive, like

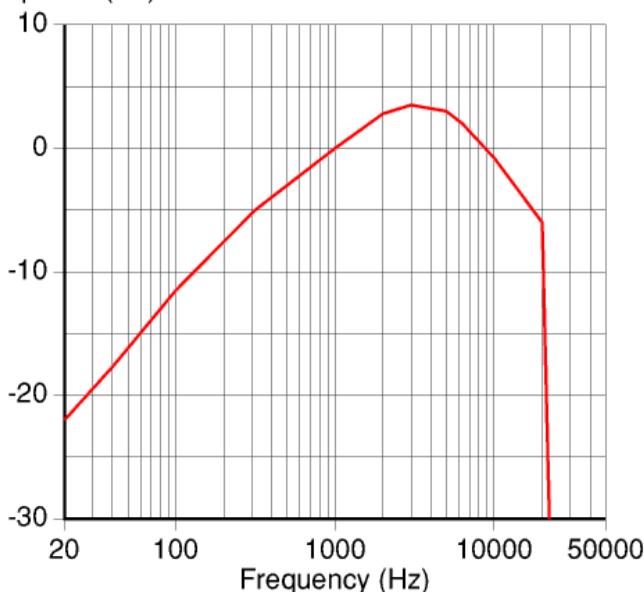

telephone line clicks. The result was a combination of frequency weighting curve and quasi-peak rectifier close to what we now call 468-Weighting.

Various bogus reasons for the shape of the 468-Weighting curve (shown above in blue) have been quoted over the years. It is often said that it was designed to reflect intrusiveness in the presence of programme, but the BBC report specifically says that the intention was to find a measure of subjective noise loudness in quiet passages. The real reason why it differs so much from the A-weighting curve (shown red) is that our ears analyse sounds in terms of frequency bands, and the loudness of noise depends

on the total energy falling in each band, as well as the way in which the outputs of the bands are combined. The higher bands have greater bandwidth, and 'gather' a bigger proportion of the total noise energy than the narrow-band low-frequency bands. This leads to the 12.2dB peak at 6.3kHz. Above this our hearing rolls off very quickly as shown in the Robinson-Dadson curve (shown green). The A-Weighting curve, though said to represent our sensitivity to tones at a low level (40 phon), actually does so rather badly, being a rough approximation to the original Fletcher-Munson curves, which were derived using headphones (side presentation). The later Robinson Dadson curves used frontal loudspeaker presentation, which is more valid. For all of these reasons, it is disturbing to find A-weighting still in use for both environmental and equipment noise measurements.

13.0 Appendix B: Crosstalk Weighting

Response (dB)

Hz	dB
40	-17.7
100	-11.5
315	-5.0
1k0	0.0
3k15	+3.5
6.3k	+2.0
10k	-0.8
20k	-6.0

Crosstalk Weighting Curve (IBA)

The above weighting curve has been recommended by the IBA (Independent Broadcasting Authority UK) for use in crosstalk measurement, and it has been used in the design of SEGc which uses the 468-Weighting filter for the measurement, but then corrects for the variation from the above, less harsh, curve, by modification of the drive level to the interfering channel. The resulting drive levels of +8dB @100Hz, 0dB @ 1kHz, -5.0dB @ 3.15kHz, and -9dB @10kHz are all within the maximum permitted levels for circuits with 50us pre-emphasis, which are:

40Hz +8.0dB, 100 +8.0, 315 +7.96, 400 +7.93, 1k +7.59, 6k3 +1.08, 10k -2.36

14.0 Appendix C: 'UniSon'

Unison is the name we have given to a proposed set of 'Unified Sonic' standards defining signal levels, interconnections and quality measurement methods applicable to all audio and audiovisual, equipment - professional or consumer. It is in four parts:

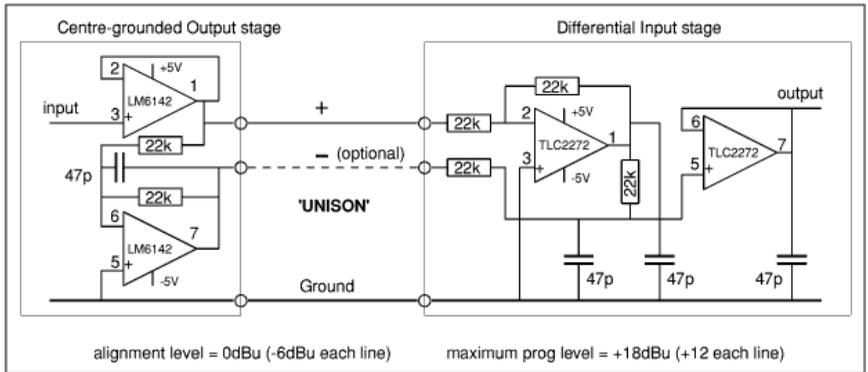

1. The UniSon Analog Levels Standard

This defines levels in terms of an assumed Alignment Level, and goes some way to improving compatibility between professional and 'consumer' equipment. Professional equipment outputs may be described as UniSon if they are balanced and centre-grounded, with an Alignment Level of 0dBu (0.775Vrms), and low impedance (10-40ohm). This allows direct connection of consumer (unbalanced) equipment between one side and ground, without any unforeseen complications, at an alignment level of -6dBu. Consumer equipment outputs may be described as UniSon if they have an Alignment Level of -6dBu, and low impedance (10-40ohm). Consumer (unbalanced) inputs may be described as UniSon if they work with an alignment level of -6dBu. Where input and output level controls are provided, the above must be true if input gain is set to read 0dB and output is set to max (also 0dB). It will be noted that some items, both professional and consumer, do already comply with UniSon requirements.

2. The UniSon Interface

Currently implemented as a 9-pin D-type connector, this combines the above specifications with a novel balanced input circuit which automatically gives 6dB more gain when only the +ve pin is connected, allowing direct connection to either professional or consumer equipment that meets the UniSon specification for Alignment Level. It also carries a 'PowerBus', permitting power at 6-8V (0.5A) to be exchanged between units, capable of powering microphone preamps, headphone amps, level convertors, and even digital convertors or even small mixers. UniSon interfaces on the MS1 allow easy connection to professional or consumer equipment, just by use of the appropriate leads. The adoption of UniSon, particularly on items such as professional and semi-pro camcorders, could bring much better quality and flexibility, solving many current problems and eliminating the need for separate mic inputs (because simple microphone adapters or mixers could pick up power in the same way that USB devices pick up power from computers). The choice of voltage range permits easy use from two-cell Lithium Ion batteries, and regulation to 5V.

A key feature of the UniSon scheme is the way in which it allows much existing equipment to be interfaced properly, just by using an appropriate connecting lead. For example, a floating balanced output can be interfaced satisfactorily to UniSon inputs, either balanced, or single ended, or both together, just by using the appropriate lead. Conventional XLR to phono adapters usually ground one side of the output, rendering manufacturers specifications invalid with the possibility of output or input clipping. They can also result in front-end overload, because while some incorporate a 10dB attenuator others just connect directly.

UniSon Input and Output circuits as implemented on the MS10

In the circuits shown above, of the MS10 input and output stages, it can be seen that the positive input is inverted and summed with the negative input, resulting in cancellation of any common-mode signal. It is the method of summing, using two resistors to form an average into a high impedance (pin 5) rather than summing in the usual way at a voltage node, which results in twice the gain (+6dB) if the -ve input is left open circuit. It is important that, if the -ve input is left open circuit, it is truly open circuit at the input socket and not fed by an open circuit lead, because the latter would introduce stray coupling at high frequencies causing response anomalies.

3. The UniSon Quality Measuring Standard

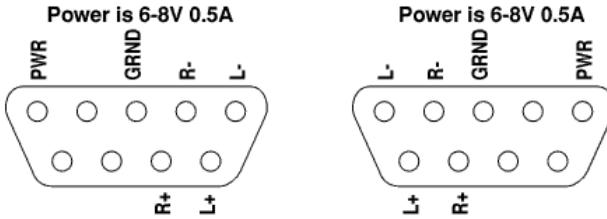

This combines the best of existing measurement standards in an attempt to make meaningful specification easy. Thus 'Noise: -66dB UniSon' is the same as saying 'Noise: -66dB measured ITU-468 Weighted Quasi-Peak relative to an assumed alignment level of 0dBu (or -6dBu single-ended).' It encompasses all items of equipment, from microphone to power amp to loudspeaker, to allow meaningful comparisons. It particularly discourages the bogus PMPO specifications so common in advertisements for active computer speakers.

This part of the standard, which can be found on the website at www.lindos.co.uk is still under development, but is essentially in accordance with the recommendations of this manual.

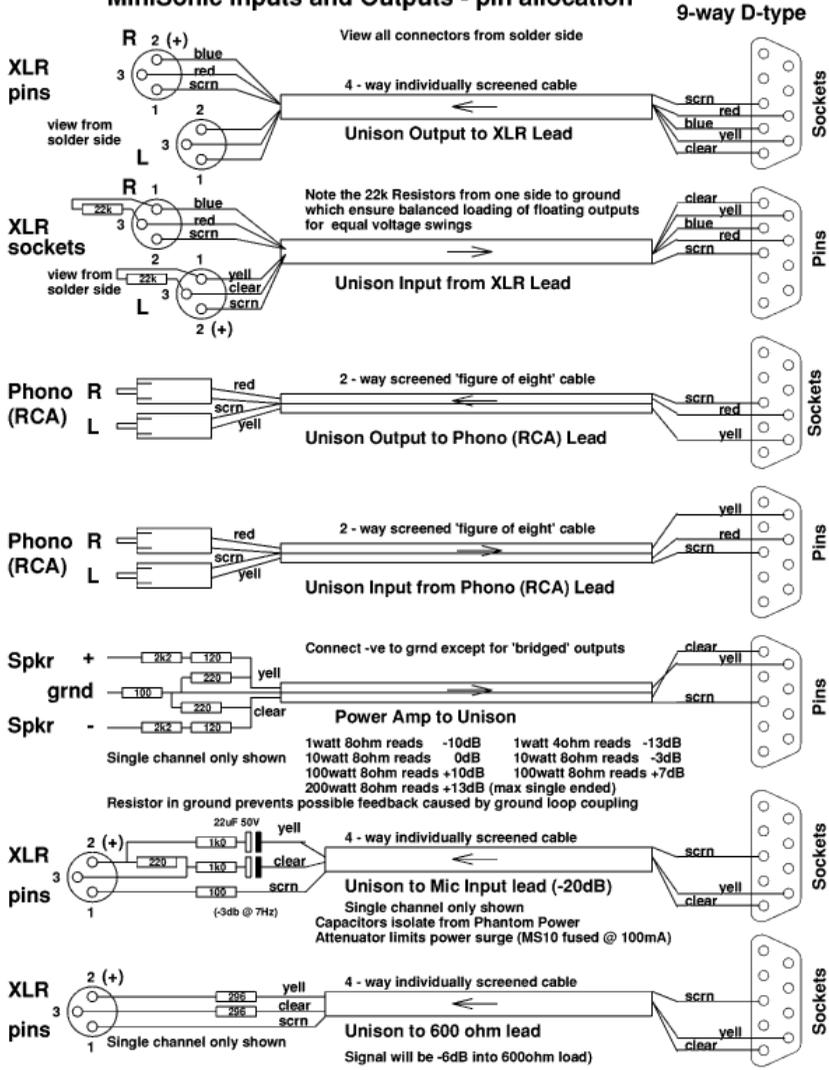

4. The UniSon Quality Grading Scheme

This sets minimum requirements for equipment to warrant a UniSon 'Grade A', or 'Grade B' quality specification (Grades 'A-', A+, A++, are also defined). The MS10 incorporates UniSon Grades in its automatic tolerance testing when used with Lin4Win as described in section 8.8. MiniSonic users can instantly view the tolerances for each grade and compare them, by simply clicking the appropriate tolerance-apply button in Lin4Win while viewing a test results sheet.

15.0 Appendix D: Connections and Leads

INPUT - sockets View from back of unit **OUTPUT - pins**
MiniSonic Inputs and Outputs - pin allocation

16.0 Appendix E: Remote Commands

Full remote control is possible using remote commands sent as ASCII characters over RS232. Lin4Win includes a 'command window' that allows easy experimentation.

General Purpose Commands

- ID?** Read Identity (returns in the form 0001 M1.0 for Minisonic 0001 V6.5 for LA100)
- TR** Total Reset
- RS** Partial Reset (leaves sequence data stored)
- RT** Reset timeout (for power down)
- D0-3** Return single binary data frame (type 0 to 3). Also cancels continuous SyncLink.
- D8** Send continuous binary data stream (SyncLink)

Oscillator Commands

- FCn** Set Output Frequency by binary code (100 = 1kHz) (0 = mute) 1/12th Octaves 4Hz to 40kHz (sets 'osclo' internally)
- FRn** Set saved frequency for restoring (after mute) ('oscsav' internally)
- LCn** Set Output Level by binary code (0 = mute 200 = 0dB) 0.5dB steps -95 to +18dB
NB this also sets the internal 'levres' value, used to res restore level after crosstalk measurements for example. Single channel commands leave this set.
- LLn** Set Output Level L chan only (codes as above) ('levsav' restore value not affected)
- LRn** Set Output Level R chan only (codes as above) ('levsav' restore value not affected)
- TBn** Generate ToneBurst, duration n ms (1 to 255) at freq and level set already

Measurement Commands

- ICn** Set input Channel (1=left 2=right 0=both) can be shortened to IC for both
- FNnm** Set measurement Function and Option: n and m are ASCII 0 to 7. m is optional.
n : 0=Phase, 1= Level, 2=Noise, 3=Crosstalk, 4=Distortion, 5=PPM, 6=Seq , 7=Freq
Option 0 is normal, eg FN1 (or FN10) is level, FN12 is ultra-fast level.
- F?** Read input Frequency in Hz (BCD ie binary coded decimal)
- L?** Read input Level in dB (ASCII decimal - CR terminated) (true value inc range)
- LF** Flag a single slow frequency measurement cycle (for frequencies below 1kHz)
- P?** Read Phase in degrees (ASCII decimal - CR terminated)
- R?** Read range (single binary byte, 0 to 120, 100=0dB, 108=+8dB etc)
- RNn** Set level range (n =single binary byte, nominal value 100 sets 0dB, 108=+8dB etc)
- NL** Normalise (as on unit) - grabs Ref level (L chan) and switches to Relative Reading.
- RL** Set read Relative Reading. RL0 restores absolute levels (not in LA100)
- O?** Read Reference level (returns two bytes, integer + 1/256 fraction dB, 100 = 0dB)
- SQn** Run a stereo test sequence. Send SQ0 to send the currently set Sequence which will normally have just been set up using multiple SGx commands
- S?n** Read Sweep graph for register r (1 = left chan 2 = right)
- SGx** Set Segment, x is the ASCII segment character, SG0 resets all segments
To set up a sequence send SG0 followed by SGn, SGu, SGr for example
- SR?** Read Sequence results (Lindos format)

17.0 Appendix F: Specifications

Analyser

Inputs Two channel 44kohm balanced or 22kohm unbalanced on 'UniSon' D-type socket (with 6-9v 0.5A 'PowerBus' for Mic preamps etc).

Level measurement Two channel simultaneous bar graph -20dBu to +9dBu (-30 to +19dBu using ranges) in 1dB steps plus 'over' and 'under'. Extended range with Lin4Win -50dBu to +19dBu with 0.01dB resolution. Accuracy ± 0.05 dB -20dBu to +19dBu. Fast Quasi-Pk reading as standard with ultra-fast option.

Vernier mode Displays one channel (selectable) plus a vernier ± 0.5 dB on the shadowbar in 0.05dB steps for precision level line-up when used as a stand-alone unit (no PC.)

Frequency mode 25Hz to 25kHz 1/3rd octave 'shadowbar' display with simultaneous level display of selected L or R channel.

Normalise Button Press and hold to normalise to any level in range +19dB to -50dB. Toggles between normalised or absolute.

PPM mode Bright, two channel simultaneous display with PPM dynamics to IEC268 type II (BBC) standard. This mode also allows for -60 to +30dB precision variable gain on the loop-through output, which has very low noise (-85dB 468-wtd Q-Pk) and distortion, for studio or location recording use.

Noise measurement ITU-468 (CCIR468-4) Weighting and Quasi-Pk dynamics, reads -40 to -70dB absolute or normalised. 0 to -90dB with Lin4Win. Residual input noise -90dBu 468- wtd.

Distortion residue Instantly normalises and then nulls the fundamental and measures the residue on a 1kHz tone weighted according to IEC268 (ITU-468 curve and Quasi-Pk detector). Display is on a fixed scale -30 to -60dB relative to normalised level. 0 to -80dB with Lin4Win, typical null depth -75dB.

Crosstalk mode Measures weighted crosstalk, automatically muting the channel selected, while driving the other at the selected frequency and level. . Any frequency or level can be selected. Reads -40 to -70dB (468-Wtd Q-Pk) as for noise. IBA weighting is applied if the crosstalk sequence is used.

Sequence mode Responds to any sequence of up to 6 test segments, as generated by the oscillator, storing results and graphical information. Used in conjunction with Lin4Win software, a complete test sheet with graphs is produced for viewing or printing, within 2 seconds of the sequence ending. In stand-alone use, it is possible to view frequency sweep information using the 'shadowbar' as up-down cursor with level readings on the main bar. Stores one set of results including 64-point two-channel plot of frequency response (or level vs level), and another 64-point single channel graph of phase (or noise vs time). Some LA100 segments are also responded to (consult Lindos for further details).

Phase display mode $\pm 180^\circ$ 20Hz - 20kHz with $\pm 2^\circ$ accuracy (up to 40kHz with reduced accuracy). Frequency sweeps also generate a graph of phase difference vs frequency.

Delay Time (Path Latency) measurement 0 to 9999ms, accuracy $\pm 0.05\%$ ± 1 ms, measured on the time taken from sending to receiving FSK when a sequence is run.

Speed and Wow and Flutter measurement indicates speed error on a 3.150kHz tone. +2% to -4% with 0.2% resolution. W&F is not currently implemented (but may be in later upgrades), indicating 0.05% to 3% Weighted Q-Pk to IEC386.

Oscillator

Outputs Two channel (10 ohm source impedance) balanced centre-grounded 'UniSon' on 9-pin D-type plug. Unbalanced when used with phono or mini-jack leads.

Freq range 4Hz to 40kHz sine in 1/3rd-octaves or 1/12th octaves, 1kHz 5kHz 10kHz square waves.

Level range -90dBu to +19dBu in 1dB steps (0.5dB with Lin4Win), balanced, centre-grounded; -96dBu to +13dBu single-ended. Accuracy ± 0.02 dB typical @0dB ± 0.05 dB typical from -60dBu to +19dBu.

Distortion -76dB Dist Residue (wtd) (-86dB/0.005% THD rms 22kHz BW) @ 1kHz typical. Minimum load 600ohms (-72dB THD).

Flatness ± 0.02 dB typical 20Hz to 20kHz, -0.05dB @31kHz, -0.6dB @16Hz and 40kHz.

Mute Mute, restore, and channel selection. Auto-mute on selecting noise measurement. Auto signal source selection on crosstalk and distortion. Residual noise -82dBu 468-Wtd.

Freq accuracy ± 0.05 % of specified synthesised frequency.

Sequences 13 Sequences instantly available from the keys including sweeps 20-20k and 40-40k, phase, noise, crosstalk, speed, dist residue at 6 levels to +18dB, noise vs time plot, headroom plot, latency, etc. A startup option provides for the generation of 4 LA100-compatible sequences. 21 MiniSonic segments, and 11 LA100-compatible segments, can be generated.

Line-up segments Special segments for repetitive GLITS and channel ident tests. Also PPM inverse-weighted tone-burst tests, etc.

Tone-Bursts Tone-Bursts 1msec to 255msec at any frequency and level are selectable from Lin4Win or by remote command.

General

Size 215 x 160 x 33 mm. Weight 600g.

Display 32-bar LED single-mark display with 'shadowbar' (reduced brightness) for R channel, cursor, or other functions.

Microphone Dual low-noise microphone inputs (2 minijacks) with 5V power calibrated to UniSon standard (?30dBu =100dB SPL. Precision calibrated miniature (1/4") mics available extra.

Remote Commands A full set of remote commands, consisting typically of an ASCII character followed by a number, allows control of operation and return of data over RS232.

'Unison' Input and output sockets carry power (6 to 9V 1A max) on 'PowerBus'.

Headphone socket 3.5mm stereo minijack for headphones 32ohm or greater. Muting of internal speaker for high quality stereo listening.

Power Slot-in Sony NP500/530/560 style rechargeable lithium-ion battery included (15hrs use) or external 12V (11-14V) smooth DC from 500mA mains adapter via 2.1mm power jack. Battery charges internally in 15hrs (half charged in 4 hrs) with power connected. PP3 with adapter gives 6hrs use.

Monitor loudspeaker Built-in 65mm speaker and volume control for listening (eg to dist-residue) - monitors left channel on all measurements.

Accessories included Manual, 'Unison' to XLR and 'Unison' to phono input and output adapter leads (1m). Lin4WinXP Windows 95/98/NT/2000/XP support software on CD.

Optional extras 'Unison' to 3.5mm Mini-jack leads, MM1 Calibrated Microphone, Test CD, test files downloadable free from Lindos Website.

18.0 Appendix G: Calibration Checking

The MiniSonic circuits, derived from 25 years of experience with our LA100 unit, are extremely stable, so that regular re-calibration is not necessary unless a problem is suspected, in which case we recommend that you run a self-test before contacting Lindos.

18.1 Self-Test

1. Connect the input and output using XLR adaptor leads (or direct UniSon to UniSon lead. Ensure that the MIC toggle is set to LINE.
2. Connect a PC running Lin4Win.
3. Check that both channels read 0dB (+/-0.05dB) on LEV at 1kHz
3. Run SEQ3 (press SEQ then key3).
4. Apply the 'MS10 Self-Test' Tolerance (see section 8.8)
5. The results should say 'PASSED' (top RHS). If 'FAIL' then an asterisk will appear by the failed measurement.

18.2 User Calibration

Self-testing is possible because the generator and measuring set in the MiniSonic are quite separate, and very unlikely to both drift out of calibration by the same amount. Provided that no major level discrepancy was noted in the above test it is reasonable to use the oscillator, which is digitally synthesised and particularly stable, as a reference by which to calibrate the measuring side. Slight differences between the A-D convertors in the PIC chips can result in small errors of level measurement when an upgrade chip is fitted, usually of less than 0.03dB, but these can be corrected by simply removing the 'chiplid' in the front panel and adjusting the two trimmers to the right of the chip until Lin4Win indicates 0.00dB on both channels (top trimmer sets L, bottom sets R). Only one trimmer is provided for oscillator adjustment (inside top cover rear LHS - but do not touch!) and Lindos set this for correct calibration on the left channel, so that the right output may be slightly in error (+/-0.05dB max). The measuring side, calibrated as above, will therefore also be slightly out on the R channel, but this is usually of no importance. It is of course possible to calibrate both inputs correctly from the L output, but this is considered less desirable (through measurements of gain are then in error).

18.3 Distortion Null Trimming

Distortion residue measurement uses a combined notch and high-pass filter to remove the fundamental 1kHz component, and this may drift slightly with temperature time, limiting the lower limit of Dist Residue measurements. The notch is easily trimmed by removing the case top (see below) and adjusting

C60 and TR2 in turn for minimum reading on DIST using Lin4Win. The two trimmers concerned are at the front of the main board next to the VOL slider control. Depending on the oscillator distortion, a reading of -75 to 82dB should be possible. Let the unit stabilise to room temperature first (we cal at 22C). A deep notch, though desirable, is not essential, as it has little effect on the accuracy of higher readings, and exceptional figures at higher levels are much less relevant than adequate readings at low levels, which on most equipment will rarely be better than -50dB .

18.4 Removing Battery and Case Top

Take out the battery by sliding it first to the left, to allow the packing foam piece to be removed, and then to the right to unlatch it before lifting out. Four Posidrive screws underneath the unit hold the plastic case-top in place. When replacing them be especially careful not to tighten the four screws beyond the point at which they just hold the top in place – further tightening will bend the PCB and case top causing battery pin misalignment. Do not force the battery in until you are sure that it has properly located over the gold pins. These should be carefully adjusted using tweezers if they get bent out of alignment.

18.5 Fitting Firmware Upgrades

From time to time Lindos may send out a free upgrade chip (PIC16F76) incorporating new features and improvements. Do not remove any screws, just prise out the plastic ‘chiplid’ carrying the ‘Lindos’ label on the front panel, using a fingernail under the RH corner. With the unit turned off, gently prise out the chip, using a small screwdriver under each end in turn, and replace it with the new one, taking care to ensure that all pins are inserted correctly (notch on the left) before pressing it home. We will re-use any old chips that are returned. Recalibration is not necessary, but for greatest accuracy it may be beneficial to carry out the user calibration and distortion nulling as above.

18.6 Fault Finding

While the MS10 inputs are well-protected, and capacitor-coupled to block DC, the oscillator outputs are protected by 5.1V Zener diodes: so connecting an output to a source of DC may blow a fuse causing total loss of output or a 6dB drop. Replacing the fuses (surface-mount 125mA 1206), which are near to the output connector (FS1-4), is tricky, but can be attempted by anyone with the necessary skills (try soldering the new fuse on top of the old one).

Lithium-Ion batteries contain a chip which protects against over-charge or over-discharge, so do not be surprised if a flat battery measures zero volts and appears to be open circuit. It is only protecting against discharge, and will still accept charge.
